Glossary

Abiotic: Nonliving.

Anthropogenic: Human-caused.

Benthic: Relating to the lake floor.

Biotic: Living.

Bottom-up control: Food web control related to chemical and physical variables of the lake, also effect of organisms with a lower trophic position than the one in question.

Branchiopoda: The taxonomical class that includes cladocerans.

Carapace: Thick, hard, chitinous shield that covers the body of most cladocerans.

Chydorid: A common group of littoral cladocerans.

Clone: A group of organisms of the same genetic constitution that are descended from a common ancestor by asexual reproduction.

Cyanobacteria: A group of bacteria formerly regarded as blue-green algae. Often in eutrophic conditions form toxic blooms in water bodies.

Dissolved organic carbon: Contributes to defining the color and ultraviolet radiation penetration in the water body.

Ephippium: The hard chitinous case covering cladoceran resting eggs.

Eutrophic: Nutrient- and biomass-rich water body.

Exoskeleton: The protective or supporting structure covering the body of cladocerans.

Gamogenesis: Sexual reproduction.

Head shield: The protective chitinous structure covering the head of a cladoceran.

Herbivore: Plant- or algae-eating organism.

Lacustrine: Refers to lakes and ponds.

Limnology: Study of fresh water.

Littoral: The shallow zone in a lake where plants are rooted, typically the nearshore region of a water body.

Melanin: The dark pigment present in cladoceran carapace, provides protection against ultraviolet radiation.

Molting: To shed the exoskeleton.

Neolimnology: Study of modern freshwaters, as opposed to paleolimnology.

Neuston: The minute organisms inhabiting the surface layer of water or moving on the surface film.

Oligotrophic: Nutrient and biomass-poor water body.

Parthenogenesis: Reproduction where offspring are formed from unfertilized eggs, with no need of males.

Pelagic: Open-water area of a lake.

Planktivore: An organism feeding on plankton.

Postabdomen: The posterior part of the cladoceran body.

Subfossil: A specimen that is found under fossil conditions but is relatively young on the geological time scale.

Top-down control: Food web control from organisms with a lower trophic position than the one in question.

Training set: A set of species collected from modern sites along with relevant environmental data. Form a basis for quantitative paleolimnological reconstruction when used in conjugation with subfossil assemblages.

Transfer function: A mathematical function that describes the relationship between biological species and environmental variables that allows the past values of an environmental variable to be inferred from the composition of a fossil assemblage.

Ultraviolet radiation: Biologically harmful radiation from the sun, wavelengths 280 to 400 nm.

Introduction

The taxon Cladocera (Crustacea: Branchiopoda) was first recognized by [Latreille \(1829\)](#), but it took 100 years more before the study of their subfossil remains was introduced into paleolimnology. The first quantitative study using animal microfossils in North America was published by [Deevey \(1942\)](#), and a few years later, DG Frey extensively promoted the use of cladoceran remains in aquatic research with his numerous publications in the mid-twentieth century (e.g., [Frey, 1960, 1964](#)). These first publications reported the occurrence of one or a few cladoceran taxa, and although they recognized the potential of cladoceran fossils as indicators of past environmental conditions, their main emphasis was to find out which species of cladocerans were preserved in sediments, how they could be

identified, and what was the general sedimentation process in a lake. The taxonomic guidelines that were set by these pioneer studies are still valid and for many species, still represent the best drawings of the remains.

Between the 1960s and 1980s, the use of cladocerans in paleolimnological research increased rapidly. Sediment cores were collected from lakes across Europe and North America with the purpose of resolving community changes in time spans varying from decades to thousands of years ([Goulden, 1964](#); [Hofmann, 1986](#)). Many of the studies also concentrated on species distribution patterns using only surface sediments ([Korhola, 1999](#)), as it was becoming evident that a single sediment sample revealed the cladoceran community composition in a water body better than a careful and extensive limnological sampling over a number of years ([Frey, 1960](#)).

These studies linked cladocerans to environmental variables such as temperature (climate), pH (acidification), and nutrients (eutrophication), initializing the use of cladocerans as indicators of past environmental conditions. However, many studies also concluded that the ecological indicator value of individual cladoceran species was variable and often rather low. Instead, interpretations should be based on the overall structure and composition of the community assemblage. The development of transfer functions in 1990s significantly increased the utility of cladocerans (and other organisms in the fossil record) in reconstructing the past. Transfer functions quantitatively reconstruct past environmental conditions in lakes. They are generated from a set of surface samples (0–1 cm depth) usually collected from >20 training set lakes, representing a large gradient of environmental conditions. Statistical correlations of the subfossil remains to environmental parameters that quantitatively identify the community response to changes of a certain environmental variable are obtained using multivariate analyses.

During the past two decades, subfossil cladoceran research has developed further by incorporating ecological processes in the reconstruction models. This means that in addition to collecting single measurements of physical and chemical variables for transfer function creation, researchers are including information such as planktivorous fish densities in their models (Amsinck et al., 2005a; Jeppesen et al., 1996). Further, the response of zooplankton to environmental conditions is not only measured in terms of species abundance and composition but also as changes in carapace size (Jeppesen et al., 2002), rates between parthenogenetic and gamogenetic reproduction (Sarmaja-Korjonen, 2004), and as shifts in clonal composition of a species (Hairston et al., 1999). Including such process, studies in paleolimnology provide new ways of studying past environments; however, the traditional method of identifying and counting remains still provides the basis for all paleolimnological work and has not lost its value.

From Living Animal to a Subfossil Remain

Organisms that are abundant in many kinds of aquatic habitats are most suitable for paleolimnological studies. Their high abundance also allows for the use of statistical methods, thus assuring a better understanding of the reliability of the reconstructions. However, living organisms become available for paleolimnological reconstructions only after their death or following processes that leave behind identifiable remains, such as molting.

The flora and fauna of lakes are made up of numerous groups of organisms that all contribute to the structure and functioning of the food web and the state of the ecosystem. Many of these organisms provide quick and reliable information on the water body in which they live. However, not all organisms are suitable as paleolimnological indicators; for instance, the remains of mobile adult insects that travel across a large set of water bodies cannot be used in the site-specific interpretation of environmental variables. Cladocerans are one of the few aquatic animal groups that are routinely used in reconstructing the past. The Cladocera are some of the primary

herbivores in lakes and contribute to the recycling of nutrients in the water column. In addition, they form a large portion of planktivorous fish and invertebrate diet. Because of their trophic position in the middle of the food web, they are subjected to both bottom-up and top-down forces and have a critical role in carbon and energy transfer through the food web.

The use of any group of organisms in paleolimnology depends primarily on their resistance to degradation after death and secondly, on the availability of features that can be used for identification. Cladocerans are moderately well preserved in sediment, and specimens of all 11 existing families leave recognizable remains. After death, cladocerans break into small fragments such as exoskeletons and ephippia, which are modified carapaces enclosing and protecting the eggs (Figure 1). Both exoskeletons and ephippia are composed of chitin, are chemically inert, and have features useful for species identification (Korhola and Rautio, 2001). Among taxonomic groups, there are great differences in the number of body parts that preserve and can be specifically identified. For most pelagic cladocerans with soft chitinous cover, the identification becomes difficult after death and many important features required for accurate identification are lost. For instance, the carapaces of *Daphnia* break into small, irregular pieces and sizes that in many cases can only be used as qualitative information of the presence of this genus in the lake. And ephippia, that are often the only remains used to quantify the *Daphnia* abundance, cannot be identified to the species level. This is unfortunate because most ecological information on living cladocerans comes from pelagic species, especially the genus *Daphnia*, and cannot be effectively used in paleolimnological interpretation. Conversely, for many littoral and benthic species, once the remains have been removed from the sediment, they reveal structures and pores that allow more accurate identification than that of intact whole individuals. Chydorid head shields are especially easy to identify to species level using the number and shape of pores that become visible in the remains after a sample preparation (Box 1).

Despite the large number of taxonomic keys available for contemporary Cladocera, the identification of their remains still relies largely on individual research papers that each scientist needs to assemble to make an identification guide. Important exceptions are the identification guides of cladoceran remains in North American lake sediments (Korosi and Smol, 2012a,b; Sweetman and Smol, 2006) and of Central and Northern Europe (Szeroczyńska and Sarmaja-Korjonen, 2007). The review paper of Korhola and Rautio (2001) also gives an extensive list of papers that serve as a good starting point in subfossil cladoceran identification.

The Indicator Value of the Cladocera

The high abundance of cladocerans in most of the world's freshwater habitats and the large range of different optimal tolerances to environmental conditions among species make cladocerans very powerful in the detection of changes in environmental conditions. The order Cladocera makes an important and abundant contribution to lake and slow running river food webs worldwide. Few species are found in brackish water, and the majority of the about 400 species are strictly lacustrine.

BOX 1 Sample preparation

Standard procedure for cleaning the sediment samples and concentrating the cladoceran remains for subfossil Cladocera analysis includes heating and stirring the sediment (usually a known volume, e.g., 1 cm^3 or 1 g) in 10% KOH for 15–30 min, washing the KOH-treated sample through a 40–50- μm mesh, centrifuging the residue, and finally staining the residue with, for example, safranin. For microscopic slide preparation, the residue is mounted on slides usually in glycerol or glycerol gelatin. Quite often, the results of the analysis are illustrated as relative proportions (%) of individual species of the total Cladocera community because proportions are irrespective of variations in sedimentation rate and water content. However, concentrations and, if the sediment core is properly dated, accumulation rates may provide additional paleoecological data on past environmental changes. To be able to evaluate concentration of the remains or individuals in the sediment samples, the residue of a known sediment volume should be brought up to a known volume (with distilled water and/or glycerol, e.g., 10 ml) after centrifuging, and a known volume of the sample (e.g., $100\text{ }\mu\text{l}$) should be placed on a slide. An alternative method to gain concentration data is to add marker grains, for example, *Lycopodium* spores within the residue, count the marker grains during the microscopic analysis, and afterward, calculate concentrations for individual taxa. A comprehensive protocol for sample preparation is presented by Szeroczyńska and Sarmaja-Korjonen (2007).

The usefulness of cladoceran remains in aquatic research is twofold. The remains in the surface sediment can be used to complement the limnological water column sampling of the modern community assemblage in lakes, and when combined with physical–chemical measurements, of environmental control of those assemblages. The down-core studies, on the other hand, use the natural lake archives to reveal the past environmental conditions in lakes.

Because cladoceran abundance varies seasonally and they occupy a variety of different habitats within a water body, their adequate representative collection with limnological sampling techniques is difficult, and many species are often overlooked. As a result, surface sediment coring from the middle of a lake

has great advantage over limnological sampling, as it integrates this seasonal and spatial heterogeneity. Cladocerans from different habitats in the littoral zone are transported offshore via currents and mixed with remains of offshore species (Frey, 1988). A surface sediment sample collected from the middle of a lake represents the entire community from all different habitats of the lake, and usually, just one sample is representative of the community structure of those species that leave sufficient recognizable remains after death. Korhola (1999) reported the cladoceran distribution pattern in subarctic Fennoscandia from single surface sediment samples per lake. In 53 lakes, he identified 29 cladoceran species, the identical number found in 17 ponds in the same geographical area as a result of extensive seasonal sampling with an average of 12 samples per site (Figure 2). Similarly, Nevalainen (2010) compared chydorid species richness and evenness in single surface sediment samples taken from sublittoral zones from nine boreal lakes with contemporary limnological sweep net samples collected weekly throughout the active period from three different habitats of the same lakes. The results showed that sedimentary assemblages clearly collect higher amounts of biodiversity with lower counting efforts than the exhaustive net sampling and analysis. Therefore, it is possible, and even more suitable, to use surface sediment assemblages in biodiversity evaluations of such aquatic organisms which preserve adequately as fossils, such as cladocerans. However, some studies have shown that there can be significant variations in species assemblages among surface sediment samples in different habitat types and depths within one lake (Kattel et al., 2007). The 33 surface sediment samples from an oligotrophic mountain loch in Scotland showed that the remains of benthic chydorid species were mostly deposited close to their original littoral habitats and that planktonic taxa accumulate to pelagic deep-water locations. Similar results are now also available from a dystrophic boreal lake from Finland (Figure 3) and further support the

Figure 2 Comparison of (a) limnological and (b) paleolimnological sampling efficiency. Limnological data is from 17 water bodies that each were sampled 12 times from ice-out to ice-in; paleolimnological data is from 53 lakes that each were sampled once. Encountered cladoceran species number per sampling (a, b) and the cumulative increase in total species number (a) are shown. Errors bars are standard errors, cumulative line is mean for the 17 sites. Limnological data from [Rautio \(1998\)](#) and paleolimnological data from [Korhola \(1999\)](#).

Figure 3 Taxon response curves (generalized linear models, GLMs) to water depth in 31 surface sediment samples in Lake Pieni-Kauro, Eastern Finland, showing the divergent depth preferences of *Alona affinis*, *Eurycercus*, and *Daphnia*. Modified from Nevalainen L (2011) Intra-lake heterogeneity of cladoceran (Crustacea) assemblages forced by local hydrology. *Hydrobiologia* 676: 9–22.

idea of heterogeneous and habitat-specific distribution of cladoceran taxa, at least in some basins ([Nevalainen, 2011](#)). Although such variability may interrupt the development of transfer functions and quantitative paleoenvironmental reconstructions, the surface sediment assemblages still remain a more efficient way of identifying the modern Cladocera community of a lake than limnological water column samples, with the restriction that they only capture species that leave remains in the sediment.

Down-core studies open the view into the past and show the greatest potential of the science of paleolimnology: reconstruction of the past. The Cladocera have existed more than 100 million years, and at least for the past 200 000 years, no morphological changes have been observed ([Frey, 1962](#); [Hann and Karrow, 1993](#)) which is essential when comparing fossil remains with modern samples. Similarly, an important factor is the measurable interaction between the Cladocera and lake abiotic and biotic characteristics. Many such interactions are well defined for cladocerans and contribute to the application of Cladocera in paleolimnology. Some of the best-defined interactions are between cladocerans and lake physical variables, especially lake perimeter, watershed area, lake depth, water temperature, and sediment organic content (e.g., [Korhola, 1999](#)). Physical and chemical parameters related to water turbidity, temperature, and conductivity control the entire cladoceran community in the water body. However, thermal structure and related nutrient and algal stratification tend to influence more pelagic populations, and macrophytes and habitat diversity influence more littoral populations, thereby making the indicator value of each species to environmental changes different.

In general, cladoceran species numbers are highest in lakes where a large range of environmental conditions allow a high number of niches and hence species, making these sites most optimal for the quantification of species–environment relationships and reconstruction of the past. Among water bodies, the greatest diversity of cladocerans is found in lakes with vast open-water areas and abundant littoral vegetation. Such habitat diversity greatly increases the number of cladoceran species present. In particular, the diverse members of the family Chydoridae are common in sites with variable substrata (macrophytes, mud, sand). The more homogenous pelagic environment usually supports fewer species than littoral and benthic habitats ([Table 1](#)). Species from the suborders Daphniidae and Bosminidae are the most commonly used pelagic species in paleolimnological interpretation.

In addition to habitat diversity and number of ecological niches available, temperature is another important controlling factor of cladoceran ecology and the most important environmental variable controlling their global-scale distributions. The abundance of Cladocera is highest in the mid-latitudes at temperatures between 15 °C and 20 °C (Gillooly and Dodson, 2000). This is the temperature range for most cladocerans that maximizes parthenogenetic reproduction, that is, a female's ability to asexually produce offspring of unfertilized eggs (Box 2). A population can multiply many times in just a few days under favorable temperatures or only produce one generation per season under marginal temperatures or not reproduce at all if the temperature is too low. For instance, *Ceriodaphnia quadrangularis* requires temperatures over 8 °C to reproduce in boreal North America. As a result of direct and indirect effects of temperature, Arctic tundra lakes are inhabited by fewer than ten cladoceran species (Bennike et al., 2005; Brancelj et al., 2009). Some species, however, are adapted to cold environments. *Daphnia middendorffiana* is restricted at the southern end of its range by a maximum temperature of around 15 °C (Patalas, 1990), and *Daphnia umbra* also favors cold mountain and tundra lakes (Schwenk et al., 2004). Temperature-mediated effects on species, composition, and population abundance are detectable in the sediments.

It is recognized that the more evolved an organism, the more complex is its interaction with the biotic and abiotic variables of its habitat. Therefore, recognizing and quantifying response signals to one specific environmental variable becomes more difficult. The presence or absence of a cladoceran in a given environment depends on two very different factors: dispersal limitation and the suitability of local environmental conditions, making the estimation of population or community response to a single environmental variable challenging. This is a source of error in predictions and interpretations. Jeppesen et al. (2001) discussed some of the pitfalls when aiming to interpret cladoceran response to a single environmental variable. Their paper gives an example of the links among climate, water level, and lake productivity that should be taken into consideration when reconstructing any one of these variables. Hence, direct effects of water level change on Cladocera are rare and need to be substantial before any significant effect can be detected. Rather, the cladoceran

BOX 2 Parthenogenetic life cycle provides a tool for paleolimnology

The lifecycle of cladocerans consists of active and dormant stages as reproduction is cyclical parthenogenesis where two reproduction modes alternate: parthenogenesis (asexual) and gamogenesis (sexual). Parthenogenesis is used under favorable environmental conditions as an efficient mechanism for population growth and maintenance. Parthenogenetic eggs develop without fertilization and genetic recombination, and consequently, the young are identical clones of their mothers (Frey, 1982; Hebert and Ward, 1972). Gamogenesis, on the other hand, occurs during periods of unfavorable environmental conditions and produces diapausal resting eggs for dormancy. Gamogenesis starts with the appearance of males (from parthenogenetic eggs) and gamogenetic females (switch from parthenogenetic females), continues with copulation, and finishes in fertilization of one or two diploid resting eggs. Accordingly, it provides a mechanism for reestablishment of populations after seasonal (e.g., winter in northern regions) or irregular (e.g., human disturbances) stresses, means for passive dispersal, and production of new genotypes via meiosis and fertilization. Although there are obvious advantages in reproducing with cyclical parthenogenesis, it is a very rare lifecycle and has extremely strict requirements for its maintenance (Lynch and Gabriel, 1983). Cladoceran resting eggs within most taxa are enclosed and protected by a morphologically modified carapace, the ephippium, and the eggs store the genetic material of the species over centuries, possibly even for longer time periods (Hairston, 1996). The resting eggs tolerate extreme events of desiccation, freezing, and digestion, and they form an egg bank in the sediment. Thus, the resting eggs in this sedimentary egg bank present an analogous pool of biodiversity to the terrestrial seed bank in plants and, additionally, provide interesting material for paleogenetic examinations (Brede et al., 2009; Limburg and Weider, 2002) and resurrection ecology (Cousyn et al., 2001; Kerfoot and Weider, 2004). Techniques are evolving to extract DNA from resting eggs. In addition, markers have been developed that allow the genotype information to be used for purposes other than just to resolve taxonomic uncertainties (Hairston et al., 1999; Schwenk et al., 2004). In favorable conditions, the resting eggs can hatch, and an ancient clone of the Cladocera can be brought back to life. This fascinating technique of resurrection ecology allows both the estimation of cladocerans to adapt genetically to changing environmental conditions and the potential to study and experiment with apparently extinct clones. So far, *Daphnia* with a big resistant ephippium has served as a test genus for such paleogenetic studies.

community responds to indirect effects of water level changes, such as substrata availability, that can be measured as a ratio of littoral habitat to pelagic habitat (macrophytes, mud, and sand vs. open water). However, in addition to changes in water level,

this ratio is dependent on temperature, which affects littoral production. Any changes in watershed dynamics that control the amount and quality of runoff also control the productivity of the littoral zone. As a consequence, changes in cladoceran community composition can be misinterpreted as an indication of water level change, when they actually arise from changes in watershed land use or temperature shifts. Inclusion of multiple environmental variables and the use of multivariate analyses help to overcome such problems in interpretation and are the norm in modern paleolimnological research.

Applications of Subfossil Cladocera in Aquatic Research

The following case studies describe the successful use of cladocerans as indicators of various environmental conditions and changes, and demonstrate the use of cladoceran subfossils in various fields of biological research. A summary of the use of cladoceran subfossil remains in paleolimnological interpretation is given in the adjoining figure (Figure 4).

Assemblage of All Cladoceran Remains

Cladoceran responses to prehistoric human settlements

Human settlement on lake watersheds has been identified as one of the key factors regulating lake production and species

community structure in lakes after the last glacial period. Cladoceran subfossil remains preserved in lake sediments were used by Szeroczyńska (1991) to estimate impacts of prehistoric settlements in three lakes in Poland. Analysis of cladoceran community changes during a time period of >10 000 years revealed several eutrophication episodes in the lakes. The first of these reflected favorable climatic conditions after the glacial period and hence allowed the initial development of cladoceran communities. Later eutrophication episodes, especially the ones that occurred during Roman and Medieval times, reflected human influence and agricultural activities on the watershed. In this study, eutrophication was inferred from the relative abundance of eutrophic–oligotrophic indicator species and from a percentage distribution of pelagic-to-littoral species. The results were cross-calibrated with the pollen record obtained from the same lakes, which indicated more frequent human settlements to have taken place on the watershed than was revealed from the cladoceran assemblage. This disparity in the results is most likely based on the different nature of pollen and cladocerans as environmental indicators. Pollen can be carried out from distant settlements, and therefore, their indicator values of the lake's trophic status may be insignificant, while cladocerans reflect actual conditions in a given water body.

Cladoceran responses to recent watershed disturbances

Cladoceran community analysis from lake sediments has also proven to have great value in evaluating lake response to

Figure 4 The use of cladoceran remains in paleolimnology. The top three boxes indicate the most commonly used applications (apart from the ephippia DNA part) and the bottom two boxes show developing techniques. More detailed information for each application is given in the text. *Daphnia* photo courtesy Patrick Van Hove (modern) and Cladocera workshop, Helsinki, 2000 (remains).

anthropogenic disturbances in shorter time scales. [Bredesen et al. \(2002\)](#) quantified effects of forest harvesting on cladoceran community assemblages in four lakes in British Columbia, Canada, that were subjected to watershed clearance ranging between 28% and 70% in the 1960s. In all lakes, the cladoceran species composition showed statistically significant changes following forest harvesting with eutrophic cladoceran taxa, for instance, *Daphnia pulex* (total phosphorus optima = $53 \mu\text{g l}^{-1}$) increasing in abundance. Based on these observed community changes, they concluded that forest-harvesting activities on the lake watershed caused nutrient changes in the water column that affected the cladoceran community via bottom-up processes. The severity of these effects depends on the topography of the area being logged and the amount of vegetation regrowth that controls the runoff of material into the lake.

Cladoceran responses to declines in lake water calcium concentrations

Calcium (Ca) concentrations are declining in many soft water lakes of the Canadian Shield and likely elsewhere ([Jeziorski et al., 2008](#)) due to complex interaction with acidification and accelerated uptake by watershed forest regrowth following tree harvesting. The Cladocera requires Ca through the use of calcium carbonate minerals as structural materials in their exoskeletons. For example, laboratory experiments have shown that *D. pulex* reproduction and survival were negatively impacted below 1.5 mg Ca l^{-1} ([Ashforth and Yan, 2008](#)). Using the Cladocera from the surface sediments from lakes in Ontario, Canada, [Jeziorski et al. \(2012\)](#) showed that within the cladoceran community, daphniids were the most responsive to Ca decline; however, responses differed within daphniid species complexes and Ca thresholds in nature appeared to be higher than those observed in the laboratory.

Size of Remains

Cladoceran size as an indicator of temperature and planktivorous fish abundance

In addition to species composition and abundance, ecological process parameters of Cladocera can be used to interpret changes in abiotic and biotic variables in the habitat. Size is one of the most commonly used process parameters. [Manca and Comoli \(2004\)](#) showed how the reduction in the range of *Daphnia* body size, measured from a head shield length, indicated time periods with cold climate and short growing season. They studied fishless mountain lakes in the Himalayas where the number of molts and *Daphnia* body size depended on the duration of the ice-free period and on summer temperatures. The results obtained from *Daphnia* stratigraphy showed a relatively strong correlation with the instrumental record of climate.

In lakes with planktivorous fish, the zooplankton size structure is influenced more by predation than temperature, with small species dominating lakes with high-predation pressure. [Jeppesen et al. \(2002\)](#) have created a transfer function to infer fish density from the size of *Daphnia* ephippia in the sediment and recently [Amsinck et al. \(2005b\)](#) tested the validity of this method in a down-core paleolimnological study in a coastal Danish lake. Their results show how the progressive eutrophication of the lake coincided with increased fish density and decreased mean size of *Daphnia* ephippia. With some

restrictions, they were also able to successfully reconstruct known fish kill incidents.

Ephippia

Ephippia production as indicator of temperature

Gamogenesis and production of resting eggs (ephippia) are considered to be under environmental control, mainly by climatic cues, although the multiple density- and predation-related factors controlling gamogenesis are only partially understood. The preservation of parthenogenetic carapaces and gamogenetic ephippia is good in the families Bosminidae and Chydoridae, allowing for a detection of variation in these two reproduction modes in subfossil assemblages. [Jeppesen et al. \(2003\)](#) showed that the ratio of ephippia and carapaces of *Bosmina* was significantly related to mean summer air temperature in a surface sediment dataset through a wide geographical transect from Greenland to New Zealand. A higher proportion of gamogenesis (ephippia) was found in colder climates. A similar relationship between mean annual temperature and *Bosmina* and chydorid ephippia was detected along a latitudinal gradient in Pan-European lakes by [Bjerring et al. \(2009\)](#). New results from a surface sediment dataset along a climate gradient from the south-boreal to the subarctic in Finland, based solely on chydorids, indicate a strong relationship between chydorid ephippia and summer temperatures ([Figure 5; Kultti et al., 2011](#)). Whether the effect of temperature on the production of ephippia is direct or indirect (food/habitat/oxygen availability) remains to be seen, but the results so far suggest that bosminid and chydorid ephippia have a powerful indicator value in the paleoclimatological research.

Using chydorids, [Sarmaja-Korjonen \(2004\)](#) used the two reproduction modes of cladocerans to estimate the length of the open-water season; high ephippium proportion is an indicator of cold climates and short open-water seasons and vice versa. Utilizing ephippium analysis and comparing the results to pollen-based temperature reconstruction curve, [Sarmaja-Korjonen and Seppä \(2007\)](#) suggested a considerable reduction in the length of the open-water season during the cold 8200 cal years BP event in Finland. Furthermore, chydorid ephippia have proven to increase and consequently indicate the harsh climate of the Little Ice Age in Finland ([Luoto et al., 2008](#)).

Subfossil genetical material reveals responses to eutrophication

To address the impact of eutrophication and the resultant increase in the abundance of nutritionally poor and toxic cyanobacteria on *Daphnia* growth rates, [Hairston et al. \(1999\)](#) combined paleolimnological methods with genetic experiments. This ingenious approach allowed them to measure *Daphnia* adaptation to eutrophication from diapausing (resting) eggs preserved in the sediments in Lake Constance in Central Europe that were hatched in the laboratory for the growth experiments. Changes in *Daphnia* clonal structure and the resultant different resistance to cyanobacteria, measured as the effect of diet on the somatic juvenile growth rate, showed that the *Daphnia* population evolved an increased ability to cope with a diet containing cyanobacteria. Genotypes from years of extensive eutrophication had higher resistance to the cyanobacteria than genotypes before the appearance of

cyanobacterial blooms. The earlier genotypes that were most heavily affected by cyanobacteria were nearly eliminated within the years of continued summertime exposure to cyanobacteria. Apart from showing that rapid adaptive evolution may significantly affect the cladoceran genetic pool, these results have important implications for paleolimnological studies because they draw attention to the still largely undiscovered potential of subfossil zooplankton remains. This is the remarkable capability of zooplankton resting eggs to store genetic

material for decades, and possibly centuries, thus providing information on species evolutionary–ecological responses to environmental change. On the other hand, these results, and the adaptive genetic response of cladocerans, raise an important question concerning the identification of fossil assemblages based on comparisons with the external morphology of modern species. Our interpretation of fossil cladoceran assemblages to reconstruct past environmental conditions rests on the assumption that these organisms have not evolved in the Late Quaternary, although increasing amount of paleogenetic evidence shows rapid evolutionary changes under environmental perturbations (e.g., Brede et al., 2009; Cousyn et al., 2001; Kerfoot and Weider, 2004; Limburg and Weider, 2002).

Chemical Composition of Cladoceran Remains

Carapace stable isotopes indicate changes in the past food web

Stable isotope analysis of different groups of organisms is routinely used in studies of food webs and ecosystem structure. Stable carbon isotopes in particular are commonly used to quantify food sources and energy flow in aquatic ecosystems, since carbon stable isotopes are known to fractionate little between each trophic transfer (Peterson and Fry, 1987). Stable nitrogen isotopes fractionate more and are typically used to infer trophic positions of consumers in food webs (Minagawa and Wada, 1984). While the technical aspects of stable isotope analysis have become easier and more affordable in recent years due to instrumental developments, this technique has only recently started to emerge in paleolimnological cladoceran studies (Perga, 2010; Perga et al., 2010; Struck et al., 1998). The main reason for the limited use of stable isotopes with subfossil organism is the relatively large sample size required per sample (minimum 0.2 mg dry weight) which means hours of microscope work picking individual remains.

Figure 5 Relationship between total chydorid ephippia (% as calculated from the sum of carapaces + ephippia) and mean July air temperature across a latitudinal climate gradient (60–70° N) in Finland. Modified from Kultti S, Nevalainen L, Luoto TP, and Sarmaja-Korjonen K (2011) Subfossil chydorid (Cladocera, Chydoridae) ephippia as paleoenvironmental proxies: Evidence from boreal and subarctic lakes in Finland. *Hydrobiologia* 676: 23–37.

Figure 6 The difference in the *Daphnia middendorffiana* carapace melanin absorbance among modern carapaces (dissected from living freshly collected *Daphnia*), subfossil carapaces (after 2.5 years under sediment), and carapaces from individuals without ultraviolet radiation exposure. The similar spectra of the modern and subfossil carapaces suggest that melanin remains chemically intact in the sediment and provides a new application for estimating past UVR conditions in lakes.

The method also still needs better validation to ensure that $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values of the carapaces reflect those of the whole body.

Perga (2010) investigated the C- and N-isotope composition of *Daphnia* and *Bosmina* carapaces and whole bodies, and found that they were strongly correlated. Carapace $\delta^{13}\text{C}$ was close to the whole body $\delta^{13}\text{C}$ for both species while carapaces of *Daphnia* were heavily (-7.9‰) depleted in $\delta^{15}\text{N}$ (carapaces of *Bosmina* were not analyzed). Using this validation, Perga et al. (2010) reconstructed the planktonic food web of an oligotrophic subalpine lake over the past 100 years. They also used other proxies and long-term biological data sets to better understand how different environmental drivers had affected the lake. An increase in the $\delta^{15}\text{N}$ values of *Bosmina* remains indicated a change in the *Bosmina* diet toward higher trophic levels, and the authors suggested that this was caused by a shift from phytoplankton diet to a diet dominated by heterotrophic flagellates. Additional studies from multiple lakes and species are required to confirm the usefulness of stable isotopes of cladoceran remains. It will be especially important to confirm that the nearly eight unit difference in $\delta^{15}\text{N}$ values between carapaces and the whole body applies to all lakes and species. Stable isotopes potentially provide another method to size structure to reveal changes in food web processes and when used with other proxies, allow a more accurate paleolimnological reconstruction.

Carapace melanin as indicator of past optical environments in lakes

Cladocerans in clear and shallow lakes have often dark-colored carapaces. The color indicates the presence of melanin pigment that the animal synthesizes when exposed to ultraviolet radiation (UVR). Rautio and Korhola (2002) have shown how the concentration of melanin in *Daphnia* is correlated to the water body-dissolved organic carbon concentration which largely defines the underwater UVR. They and Jeppesen et al. (2001) have suggested that carapace melanin could be measured in subfossil *Daphnia* remains and used as an indicator of changes in the past optical conditions in lakes. In order to use cladoceran melanin as a paleolimnological indicator, it is essential to know whether the melanin is chemically inert in the carapace after death. This information is now available (Figure 6) and provides a new challenging cladoceran indicator, ready to be applied in down-core studies.

Conclusions

The usefulness of cladocerans as environmental indicators and their success in paleolimnological interpretation arises from the diversity and abundance of their fossil remains, from the high intraspecies variability in reaction to different environmental changes and from their short generation time and consequent rapid response (days to weeks) to any shifts in the environment they inhabit. There are many mechanisms that link environmental parameters to cladoceran community composition in a water body. Some are caused by regional climate and temperature-induced changes and work both via direct and indirect mechanisms, while many are associated

with components of a single water body, notably with changes in water chemistry, and in physical parameters associated with watershed and water column properties. As shown in the many examples summarized here, these effects are likely to be reflected in cladoceran species composition and abundance or in more subtle ways in clonal structure or pigmentation of the species, that advancing technology has only recently been able to quantify.

Freshwater Mollusks

C G De Francesco, CONICET – Universidad Nacional de Mar del Plata, Mar del Plata, Argentina

© 2013 Elsevier B.V. All rights reserved.

Introduction

Freshwater mollusks (Phylum Mollusca) are among the most ubiquitous macroscopic remains preserved in continental Quaternary sediments. They are exclusively represented by gastropods (Class Gastropoda) and bivalves (Class Bivalvia). With the only exception of opisthobranchs (Class Gastropoda), all have an external calcareous shell (of one or two pieces, respectively) which is generally the only fossilizable structure in the sedimentary record (Figure 1). Indeed, the freshwater mollusk evidence from the Quaternary usually involves unaltered shells, in contrast to fossils from older deposits that mainly consist of molds or casts.

The fossil record of freshwater mollusks is characterized by low diversity compared to the marine record due, in part, to poorer preservation of organisms as well as the ephemeral nature of many freshwater habitats (Taylor, 1988). Fossilization is biased toward lowland and lake deposits, which are low-energetic environments where fossilization is favored. Fossiliferous river deposits are fewer than those of lakes, and the record is negligible or absent for such habitats as upland seepages, springs, and subterranean streams (Gray, 1988). This incomplete record is also due to the poor preservation potential of the often light, thin shells of most freshwater taxa. In fact, the fossil record of freshwater gastropods is patchy at best and likely to significantly underestimate the age and diversity of freshwater lineages (Strong et al., 2008).

Despite these difficulties, assemblages of mollusk shells can add important information to paleoecological and paleolimnological reconstructions (Gray, 1988). They have been widely used to reconstruct ancient local habitats and climatic conditions in combination with other biological and sedimentary proxy records. A number of modern studies have focused on the analysis of stable isotopes ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) for inferring past temperatures, evaporative effects, and productivity levels. Much recent work has been directed to the evaluation of the processes and agents involved in the genesis of fossil assemblages, such as their compositional fidelity and taphonomy. The aim of this chapter is to review the main research directions associated with Quaternary freshwater mollusks that contribute to make them effective paleolimnological indicators. An overview of the present status of research, advances in methodology, as well as the problems and possibilities of every research direction are presented and discussed. Some case studies are also presented that exemplify various applications in fossil reconstructions.

Taxonomy

Most taxa encountered as fossils in Quaternary freshwater deposits are referable to extant species (Figure 2). Consequently, their reliable identification requires a good knowledge of the

taxonomy of modern fauna. Bivalves and gastropods include a variety of groups derived independently from marine ancestry, and varying in range of habitat, reproduction, and distribution.

Mollusk taxonomy is rather complicated and is at present being substantially revised. New suites of anatomical, ultrastructural, and molecular characters developed in the past 30 years have fuelled a revolution in our understanding of gastropod phylogenetics (see Bouchet and Rocroi, 2005 and references therein). The current understanding of the phylogeny of bivalves is still developing (Bogan, 2008).

Bivalves

Bogan (2008) listed a total of 19 families with 206 genera and an estimated 1026 species of freshwater bivalves (Table 1). Freshwater bivalves are found in three subclasses: Pteriomorpha, Paleoheterodonta, and Heterodonta. The Pteriomorpha, mainly a marine group, is only represented in freshwater by four species of Arcidae (genus *Scaphula*) in India, Burma, and Thailand and by five species of Mytilidae. The Paleoheterodonta include the order Unioniformes, which is one of the groups with larger radiations in freshwater. Within this order, the most diverse family is the Unionidae. Bogan (2008) estimated a total of 621 species worldwide, while Graf and Cummings (2007) calculated approximately 674 species. Two main areas exhibiting high diversity and endemism are the southeastern United States and southern Asia. In fact, a maximum of 42 genera and 271 species of unionids were reported for the southeastern United States. On the other hand, the Hyriidae and the Mycetopodidae account for the majority of bivalve faunal diversity in South America. The subclass Heterodonta encompasses numerous families, each having only 1–5 genera and species. Exceptions are the Sphaeriidae and Corbiculidae, with larger radiations. A maximum of 196 species of Sphaeriidae has been described, most of them in South America (Bogan, 2008).

Gastropods

Gastropods are more diverse than bivalves, with a total fauna estimated at approximately 4000 valid species. By far, the most diverse group is the Rissooidea. While most families are probably known within 70–90% of actual diversity, the estimated 1000 species of Rissooidea may represent as little as 25% of their actual diversity, as evidenced by the fact that they comprise about 80% of current new species descriptions (Strong et al., 2008).

The freshwater gastropod fauna is dominated by two main components: the Caenogastropoda and pulmonate heterobranchs (Table 2; Bouchet and Rocroi, 2005). Some Neritimorpha (Neritiliidae, Neritidae; previously a subgroup of 'archaeogastropods'; Bouchet and Rocroi, 2005) have also invaded freshwater.

Figure 1 Shell characteristics of gastropods (left) and bivalves (right).

Modified from Martínez SA and Rojas A (2004) Quaternary continental molluscs from Northern Uruguay: distribution and paleoecology. *Quaternary International* 114: 123–128; De Francesco CG and Hassan GS (2009) The significance of molluscs as paleoecological indicators of freshwater systems in central-western Argentina. *Palaeogeography, Palaeoclimatology, Palaeoecology* 274: 105–113, with permission.

The Caenogastropoda (for many years named Prosobranchia and containing most of the former Mesogastropoda and all the Neogastropoda) share a few (probably ancestral) characters: they breathe through gills, carry an operculum (which sometimes fossilizes), and are usually gonochoristic (separated into two distinct sexes) and occasionally parthenogenetic (reproduction through the development of unfertilized eggs), but only rarely hermaphroditic (having both male and female reproductive organs in the individual). Caenogastropods have invaded freshwaters on at least as many occasions as the number of their superfamilies. The families Viviparidae, Pleuroceridae, Hydrobiidae, and Pomatiopsidae are worldwide in distribution. The Melanopsidae and Bithyniidae are both restricted to the Eastern Hemisphere. The Ampullariidae and Thiaridae are circumtropical, with distributions reaching to the subtropics (Dillon, 2000).

The Heterobranchia (containing the former Opisthobranchia and Pulmonata, as well as the so-called Allogastropoda or 'lower Heterobranchia'; Bouchet and Rocroi, 2005) include all the remaining gastropod families. Within this group,

pulmonates are the most abundant. They have lost their gills and now respire over the inner surface of their mantle, effectively a lung (some groups also developed a secondary gill). They typically have much lighter shells than caenogastropods and lack an operculum. In addition, they are hermaphroditic. All freshwater pulmonate families belong to the Basommatophora, so named because their eyes are at the base of their tentacles. They seem to have derived from a single ancient invasion of freshwater, dating at the latest, to the Jurassic period. Minor families (including the limpet-shaped Acroloxidae) are held to be the most ancestral of the freshwater pulmonates, by virtue of anatomical detail. The worldwide Lymnaeidae, with their rather ordinary looking, dextral shells of medium to high spire, are believed the next most ancestral. Members of the primarily holarctic Physidae are distinguished by their inflated shells coiled in a left-handed ('sinistral') fashion, quite unusual in the class Gastropoda. Members of the worldwide Planorbidae are also sinistral, but often planispiral (coiled in one plane, like a flat spiral; Dillon, 2000). They include the limpets previously separated as Ancyliidae.

Table 1 Taxonomic classification and total number of valid, described genera and species of freshwater bivalves

<i>Subclass</i>	<i>Order</i>	<i>Family</i>	<i>Genera/species</i>	<i>Examples</i>
Pteriomorpha	Arcoida	Arcidae	1/4	<i>Scaphula pinna</i>
	Mytiloida	Mytilidae	4/6	<i>Limnoperna fortunei</i>
Paleoheterodonta	Unioniformes	Etheriidae	1/1	<i>Etheria elliptica</i>
		Hyriidae	17/83	<i>Diplodon patagonicus</i>
		Iridinidae	6/41	<i>Mutela rostrata</i>
		Margaritiferidae	3/12	<i>Margaritifera margaritifera</i>
		Mycetopodidae	12/39	<i>Anodontites trapesialis</i>
		Unionidae	142/621	<i>Elliptio complanata</i>
Heterodonta	Veneroida	Cardiidae	2/5	<i>Adacna laeviscula</i>
		Corbiculidae	3/6	<i>Corbicula fluminalis</i>
		Sphaeriidae	5/196	<i>Sphaerium simile</i>
		Dreissenidae	2/4	<i>Dreissena polymorpha</i>
		Solenidae	1/1	<i>Pharella waltoni</i>
		Donacidae	2/2	<i>Egeria paradoxa</i>
		Novaculidae	1/2	<i>Novaculina siamensis</i>
	Myoida	Corbulidae	1/1	<i>Guianadesma sinuosum</i> ^a
		Erodonidae	2/2	<i>Erodona afra</i>
		Teredinidae	1/1	<i>Nausitora dunlopei</i>
		Lyonsiidae	1/1	<i>Anticorbula fluviatilis</i>

^aHuber (2010) considered this species a junior synonym of *Anticorbula fluviatilis*. This lowers the total number of families represented in freshwater to 18.

			Planorbidae	250	<i>Ancylus fluviatilis</i>

Classification follows Bouchet and Rocroi (2005). Data on species abundance from Strong et al. (2008).

It is very common that a single species may occur in a wide variety of water bodies because it is eurytopic (or a generalist) and has a wide tolerance to a particular variable. Even species considered to be stenotypic, or limited in their environmental tolerances, may occasionally occur well outside their normal range (Ellis, 1940). An example of this is the limpet *Ancylus fluviatilis*, which lives on clean stones in quickly running streams. This led Sparks (1964) to conclude that the interpretation of freshwater mollusk paleoecology becomes a matter of relative probability. The corbiculid clam *Corbicula fluminalis*, a conspicuous bivalve present in the Pleistocene of North-West Europe, principally inhabits freshwater habitats, but there is evidence that it could also tolerate mildly brackish conditions (Meijer and Preece, 2000). The thiarid gastropod *Melanoidea tuberculata* occurs abundantly in a wide range of modern and Quaternary fresh and brackish water habitats throughout Africa and Asia. In highly evaporated lakes, too saline for most freshwater organisms, *M. tuberculata* is often the only mollusk present (Leng et al., 1999; Pointier et al., 1992). Similarly, the rissoiidean snail *Heleobia parchappii* lives both in fresh and saline water. When this species occurs in saline water, it is the only mollusk present; however, when in freshwater, it is usually accompanied by other mollusk species (De Francesco and Hassan, 2009). These euryhaline species (having a wide range of tolerance to salinity) still bring some important advantages as paleobioindicators. Although the species from freshwater habitats cannot be morphologically distinguished from those inhabiting saline waters, the overall composition of the whole assemblage may be indicative of these two habitat extremes. In fact, the presence of monotypic deposits of any of these species (Figure 4) would be indicative of elevated salinity in the past.

Examples of paleolimnological reconstructions based on the paleoecology of freshwater mollusks are found worldwide. Yang et al. (2001) studied the mollusk assemblages recovered from two Holocene marl deposits in southwestern Ontario (Canada), indicating cool shallow vegetated water bodies. As the authors found some differences between cores obtained at different depths, they recommended a minimum of two sampling sites from any given sedimentation basin, near shore and mid-basin, to maximize the assessment of assemblages and to obtain a more reliable paleolimnological reconstruction. Similarly, Martínez and Rojas (2004) found differences in species diversity in Pleistocene fossil assemblages of northern Uruguay that correlated with the variety of sub-environments represented. Oswald (2006) reconstructed the variations in depth of an arctic shallow lake during the

mid-Holocene based on the presence and abundance of two species of Sphaeriidae indicative of shallow water (*Pisidium nitidum* and *P. rotundatum*). De Francesco et al. (2007) reconstructed the hydrological dynamics of a very shallow vegetated water body in a Pleistocene alluvial succession from Mendoza (Argentina). According to the alternation between assemblages of aquatic and hygrophilous land snails, they recognized four main stages indicating occasional submersions within a semi-temporary regime (Figure 5). More recently, De Francesco and Hassan (2009) discriminated between two mollusk assemblages indicative of different energetic environmental conditions related to the stability of the flow regime: (1) lentic habitats (shallow lakes) or calm backwaters (pools) within lotic systems such as streams and rivers and (2) lotic habitats where a directional water flow exists. These same groups were recognized in the fossil record, allowing the reconstruction of habitats that differed in the magnitude of water flow. Similar differences in hydrological regime have been reported by Grimley et al. (2009) for a Pleistocene lacustrine section in western Tennessee, USA. Here, a change from a permanent lake phase at ca. 24–23.6 ka to a marsh/shallow lake environment at circa 23.6–23.1 ka is suggested by the replacement of aquatic snails (e.g., *Ammicola limosa*, *Gyraulus parvus*, *Valvata tricarinata*) by amphibious species (*Pomatiopsis lapidaria*, *P. scalaris*, *Fossaria dalli*, *F. parva*).

Stable Isotopes

Freshwater mollusks are also very useful to evaluate paleoenvironmental and climatic conditions through the analysis of the variations in stable isotope composition recorded in the shell carbonate. To allow paleoenvironmental inference, shell carbonate should be deposited at or near isotope equilibrium with the ambient water. This enables differentiation between environmental and intrinsic organism variation (a condition referred to as ‘vital effects’). Examples of both isotope equilibrium and disequilibrium precipitation have been reported for freshwater mollusks. Shanahan et al. (2005) illustrated the potential complexities of interpreting stable isotopic data from fossil gastropod shells, even when environmental conditions are nearly constant, and placed limitations on the paleoenvironmental deductions that can be made. They also suggested that explaining the differences between the shell isotopic compositions of lung- and gill-breathing snails requires a combination of both behavioral and physiological factors.

Figure 4 Monotypic shell concentrations of *Heleobia parchappii* as indicators of elevated salinity in the past. Left: Modern death shell assemblages in a saline stream. Right: Holocene assemblages in an outcropping alluvial succession.

Figure 5 Relative abundances of species, and total densities of mollusk shells from La Bomba sequence (Pleistocene). The alternation between levels dominated by freshwater pulmonate snails (*Biomphalaria peregrina* and *Lymnaea viator*) and levels dominated by hygrophilous land snails (*Succinea meridionalis*, *Radiodiscus* aff. *Radiodiscus quillajicola*, and *Rotadiscus amancaezensis*) allows one to recognize the evolution of an ephemeral shallow water body subject to periodical droughts. Adapted from De Francesco CG, Zárate MA, and Miquel SE (2007) late Pleistocene mollusk assemblages and inferred paleoenvironments from the Andean piedmont of Mendoza, Argentina. *Palaeogeography, Palaeoclimatology, Palaeoecology* 251: 461–469, with permission.

Oxygen Stable Isotopes ($\delta^{18}\text{O}$)

As the oxygen isotope composition of shell carbonate usually precipitates in isotopic equilibrium with ambient water, and because physiological effects are often minor, oxygen isotopes provide useful estimates of environmental temperature change by indicating the effect of temperature on evaporation. Relatively high values, for instance, may be interpreted as indicating high evaporation/precipitation ratios, which are considered to reflect relatively warm, dry conditions, while relatively low values could indicate cooler and moister times (Stuiver, 1968). Yet, Fastovsky et al. (1993) observed that the unionid bivalve *Elliptio complanata* does not secrete aragonite in oxygen isotopic equilibrium with the water in which it grows. Similarly, Shanahan et al. (2005) found that even in springs with uniform environmental conditions, variation in isotopic composition of several species of freshwater snails exceeded predicted values. Therefore, paleoclimatic inferences based on oxygen isotopes should be performed with great caution, taking into consideration the vital effects of particular species.

The application of $\delta^{18}\text{O}$ values of freshwater shells as paleoclimatic indicators has resulted in some significant contributions. As an example, a succession of $\delta^{18}\text{O}$ values in a 37-m core obtained from the crater lake of Valle di Castiglione (near Rome) allowed discrimination between two climatic phases. The succession of $\delta^{18}\text{O}$ values in the core interval 37–2.3 m ranged from -2.8 to $+6.9\text{‰}$ with only six samples below 0‰ , indicating arid climatic phases. In contrast,

only negative $\delta^{18}\text{O}$ values (from -13.3 to -0.5) were found above this level, corresponding to wet climatic periods, in agreement with a strong evaporative control on the lake water isotopic composition (Zanchetta et al., 1999). In another example, the existence of arid conditions between 35 and 15 ka BP and warmer conditions around 35–25 ka BP was suggested for the Pampa and Patagonia regions of Argentina from the analysis of $\delta^{18}\text{O}$ composition of freshwater gastropod shells (Bonadonna et al., 1999).

Carbon Stable Isotopes ($\delta^{13}\text{C}$)

Stable carbon isotope data of freshwater shells have historically been used as proxies of photosynthesis, respiration, decay, and paleoproductivity (see Miller and Tevesz, 2001 and references therein). However, the interpretation of $\delta^{13}\text{C}$ composition remains controversial. This is because both respired CO_2 and ambient inorganic carbon contribute to mollusk shells and the relative importance of each source will determine whether $\delta^{13}\text{C}$ records mainly dietary $\delta^{13}\text{C}$, or the $\delta^{13}\text{C}$ of ambient dissolved inorganic carbon (DIC). Shanahan et al. (2005) found that for lung-breathing pulmonate gastropods, shell $\delta^{13}\text{C}$ mainly reflects diet. On the other hand, shell $\delta^{13}\text{C}$ of gill-breathing mollusks mainly reflects DIC and, therefore, may record changes in pH, temperature, or salinity (Fritz and Poplawski, 1974; McConnaughey and Gillikin, 2008; Shanahan et al., 2005). However, in some gill-breathing

unionids as well as in the pearl mussel *Margaritifera margaritifera*, the use of $\delta^{13}\text{C}$ shells as a recorder for environmental signals is questionable since they are strongly influenced by individual metabolic activity (Dettman et al., 1999; Geist et al., 2005). Wurster and Patterson (2001) suggested that $\delta^{13}\text{C}_{(\text{shell})}$ values appear to be related to physiological variables such as metabolic activity, trophic position, and/or reproduction, which may have significant implications for evolutionary and physiological studies, for both extant and extinct species. Because of the many different possible origins of shell $\delta^{13}\text{C}$ (environmental CO_2/O_2 ratio, DIC content, or the animal's physiology), the proper interpretation of records depends on context (McConnaughey and Gillikin, 2008).

Strontium Stable Isotopes ($^{87}\text{Sr}/^{86}\text{Sr}$)

Another stable isotope ratio that has received less attention than $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ but is at times employed in paleolimnological reconstructions is the $^{87}\text{Sr}/^{86}\text{Sr}$ ratio. Mollusk shells are rich in calcium carbonate and strontium, the latter documenting the strontium ratio of water from which they were deposited if samples were not subject to geochemical reactions after mineral formation (Reinhardt et al., 1998). Because of similar atomic weights, ^{87}Sr and ^{86}Sr do not fractionate

measurably during natural chemical reactions or physical transformations. The study of strontium ratios has been successfully applied to the study of ancient lake evolution in a number of places (e.g., Fan et al., 2010; Hart et al., 2004; Rosenthal et al., 1989).

Sample Size Effects

The number of shells analyzed may contribute to mask interpretations of environmental change. Jones et al. (2002) found differences in $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values between two coexisting snails (*G. piscinarum* and *Valvata cristata*) in an 8-m sediment core taken at Lake Gölhisar, Turkey (Figure 6). Covariation between $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ suggested that carbon incorporated into the shells was not substantially derived from metabolic carbon but rather from DIC in the lake water. They interpreted these results as a spatial (i.e., microhabitat) or temporal (time of calcification) effect. Lake water $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ have been shown to change annually. Consequently, Jones et al. (2002) suggested that only by analyzing a sufficient number of individual shells from each level in a given sequence can a reliable interpretation of environmental change be obtained. Studies where only one or two shells per level are analyzed are unlikely to provide a true indication of the variability within the period

Figure 6 Variations in $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ shell composition of two snail species in an 8-m sediment core from Lake Gölhisar (Turkey). The range of values for *Gyraulus piscinarum* (squares) and *V. cristata* (triangles) at each sample level are shown with a trend line running through the midpoint of each level for isotope zones 1–3 (Iz 1–3). Sample levels where significant numbers (≥ 4) of both species were analyzed are bracketed (bracketed values are one standard deviation either side of the given values). The more positive $\delta^{18}\text{O}$ values recorded in isotope zones 2 and 3 reflect periods of greater aridity, when lake water was more strongly evaporated. On the other hand, the more negative values observed in isotope zone 1 reflect more positive water balance within the lake system and, probably, higher humidity. In the three levels where both species were analyzed in significant numbers, $\delta^{13}\text{C}$ and to a lesser extent $\delta^{18}\text{O}$ values for *V. cristata* were always more positive than those of *G. piscinarum*. This difference was interpreted as a spatial (i.e., habitat) or temporal (time of calcification) effect. Adapted from Jones MD, Leng MJ, Eastwood WJ, Keen DH, and Turney CSM (2002) Interpreting stable-isotope records from freshwater snail-shell carbonate: A Holocene case study from Lake Gölhisar, Turkey. *The Holocene* 12: 543–548, with permission.

Figure 7 Micromilling of a valve of *Elliptio* sp. for sclerochronological analysis. The valve surface is physically cleaned to remove the periostracum, prismatic layer, and any exterior contamination. Adapted from Carroll M, Romanek C, and Paddock L (2006) The relationship between the hydrogen and oxygen isotopes of freshwater bivalve shells and their home streams. *Chemical Geology* 234: 211–222, with permission.

represented by the sample. This is especially true of small lakes in which there are potentially large temporal variations in lake water-isotope values.

Sclerochronology

As shell carbonate is deposited continually over the lifetime of the organisms, the analysis of the ontogenetic variations in $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values along skeletal growth lines of fossil and recent mollusks can be used as a high-resolution proxy to reconstruct variations in aquatic environments, as well as to characterize the physiology of the CaCO_3 secreting organism. Recent technological advances permit microsampling of carbonate to obtain records with subannual and even daily resolution (Figure 7). This is the main focus of sclerochronology, a discipline originally defined as the skeletal equivalent of dendrochronology (Hudson et al., 1976). Sclerochronology may be referred as the study of physical and chemical variation in the accretionary skeletons of organisms.

Sclerochronology has mainly been developed in marine and estuarine organisms. Yet, in the last decade, a growing number of studies have included freshwater mollusks. Wurster and Patterson (2001) investigated the suitability of two lacustrine bivalves, *Sphaerium simile* and *Dreissena polymorpha*, for recovering paleoenvironmental records on daily to weekly time scales (Figure 8). As relatively short-term temperature variability was faithfully recorded, they concluded that the seasonal pattern in the $\delta^{18}\text{O}_{(\text{shell})}$ values is a powerful tool for interpreting past climates. Variations in annual shell growth of the pearl mussel *M. margaritifera* allowed the reconstruction of summer (June–August) air temperatures for each year over the period AD 1777–1993 (Schöne et al., 2004). Helama and Nielsen (2008) demonstrated that sclerochronological reconstruction based on statistically reliable growth variability is also possible, not only through the analysis of live-collected material but also using subfossil shells. In fact, Leng et al. (1999) analyzed the ontogenetic variations in $\delta^{18}\text{O}$ values along skeletal growth lines of modern and fossil shells of the freshwater-brackish snail *M. tuberculata*. Results indicated that the isotopic composition of early Holocene rainfall in the Ethiopian Rift Valley was slightly more negative than that of the present day,

Figure 8 Short-term temperature variability recorded in the shell of the fingernail clam *Sphaerium simile*. The $\delta^{18}\text{O}$ values show a seasonal pattern. A plateau with minor variation in $\delta^{18}\text{O}$ at 9.3–10.1 mm indicates that the organism does not accrete CaCO_3 during the winter months. The increase in $\delta^{18}\text{O}$ toward most recent times (13 mm) reflects a brief warming period that took place toward the end of 1999. VPDB = Vienna Pee Dee Belemnite. Adapted from Wurster CM and Patterson WP (2001) Seasonal variation in stable oxygen and carbon isotope values recovered from modern lacustrine freshwater molluscs: Paleoclimatological implications for sub-weekly temperature records. *Journal of Paleolimnology* 26: 205–218, with permission.

suggesting a greater influence of summer rainfall derived from the Atlantic monsoon. Also by analyzing isotope variations in shells of *M. tuberculata*, Smith et al. (2004) concluded that, during the Pleistocene, the currently hyperarid Western Desert of Egypt was subject to significantly wetter conditions (high precipitation) than present.

Hydrogen isotope ratios (as δD : the ratio of 2H to 1H in a sample vs. in a standard) are another proxy used to assess paleoenvironmental conditions. Hydrogen isotopes are fractionated in natural waters by the same mechanisms as oxygen isotopes, though to a lesser extent, due to the lower relative mass difference in isotope species. The δD of the organic matrix in mollusk shells potentially offers an independent proxy for the $\delta^{18}O$ value of water and therefore a method to improve $\delta^{18}O$ paleoenvironmental interpretations in freshwater systems. Although Carroll et al. (2006) demonstrated the potential of this technique to reconstruct paleoenvironments through the analysis of freshwater mussel shells, it has not been applied at present in paleolimnological research.

Taphonomy

Since the early 1980s, extensive research conducted in contemporary marginal marine settings demonstrated a good correlation between taphonomic conditions of shelly remains accumulating in local death assemblages and the type of depositional environment (see review in Best and Kidwell, 2000). These actualistic studies fundamentally advanced our understanding of fossilization processes and enhanced our knowledge of how shell preservation varies, both among environments, as well as within single homogenous habitats.

The development of taphonomic studies in freshwater habitats has been scarce and restricted to certain regions of the globe, while other regions have remained practically unexplored. The scarce taphonomic studies carried out thus far on freshwater mollusks have focused on the quantitative fidelity, taphonomic signatures, and spatial fidelity of assemblages found in lacustrine and fluvial environments.

Quantitative Fidelity

The quantitative fidelity is the quantitative faithfulness of the record of morphs, age classes, species richness, species abundances, trophic structure, etc., to the original biological signal (Behrensmeier et al., 2000). In other words, it is the degree of similarity between the life assemblage and the potential death assemblage. A high fidelity between unionid live and dead assemblages has been reported in a variety of streams and reservoirs in east-central Ohio (Cummins, 1994). The death assemblage also preserved the rank orders (live/dead) of abundance and biomass of the preservable mollusk components in some environments, but not in those that were most environmentally disturbed. Similarly, surveys of living mollusks and dead assemblages undertaken at River Lech (Austria) also showed a high fidelity and indicated that most accumulating death assemblages were of entirely local provenance (Briggs et al., 1990). More recently, the analysis of the present-day mollusk assemblages occurring in straight and meandering sectors of the Touro Passo River (Brazil) indicated high ecological fidelity (Martello et al., 2006). The taxonomic composition and some features of the structure of communities, especially the dominant species, also reflected some ecological differences between the two main sectors sampled, such as the complexity of habitats in the meandering sector.

In a recent contribution, Erthal et al. (2011) found that fossil assemblages (Pleistocene–Holocene) from the Touro Passo Formation differed strongly from both living and death assemblages of the Touro Passo River in species composition (identities), rank abundance, and proportional abundance of species. This poor fidelity is driven by (1) taphonomic processes, which favor the long-term preservation of thick-shelled species; (2) human-induced changes in freshwater environments, such as the introduction of invasive alien species (e.g., *C. fluminea*); and, to a lesser extent, (3) the differences in the magnitude of time averaging. The results obtained by Erthal et al. (2011) have implications for conservation paleobiology. Comparing the compositional fidelity among living, death, and Quaternary fossil assemblages allows us to detect the decline of some species and/or to determine baselines for recovering their original biodiversity, contributing to programs in conservation biology.

Taphonomic Signatures and Spatial Fidelity

Shells of freshwater mollusks are expected to acquire diverse postmortem alteration because they are vulnerable to processes that operate in high-energy fluvial or lacustrine systems (Figure 9). The type of taphonomic signature that can be quantified in shells varies from author to author, depending on the taxa analyzed. Among the most commonly used are presence of articulation (only for bivalves), degree of fragmentation, shell texture (the alteration of shell surface by abrasive or dissolutive processes), encrustation (percentage of encrusting organisms on the shell), and bioerosion (percentage of bioerrosive marks in the shell). The presence of 'proteinaceous parts' (Kotzian and Simões, 2006), that is, the presence of periostracum, ligament, and operculum, is another very useful signature for freshwater shells. As abrasion and dissolution may act together in shell destruction, they are sometimes grouped in one category, namely, 'corrosion' (see Brett and Baird, 1986).

The taphonomic signature of dead shells has provided useful insights into the extirpation of freshwater mussels associated with mercury pollution in the North Fork Holston River, Virginia, USA. In fact, the degree of shell alteration proved to be a reliable predictor for distinguishing affected and unaffected sites along the river. Upstream areas that have had a continuous input of recently dead shell material exhibited younger taphonomic signatures. A site located directly below the contamination source exhibited the oldest taphonomic signature. This site had been devoid of viable populations for at least 30 years and thus was likely to be dominated by old specimens that have been altered by the prolonged action of various taphonomic factors operating in fluvial systems. The areas downstream exhibited an intermediate taphonomic signature, likely reflecting the fresh-dead shell input from mussels reintroduced in postindustrial restoration efforts (Brown et al., 2005).

Differences in some taphonomic signatures (disarticulation, fragmentation, edge rounding, proteinaceous remains, encrustation, precipitation, and corrosion) were compared between two fluvial subenvironments (straight versus meandering to braided sectors) in the Touro Passo River (Brazil) (Kotzian and Simões, 2006). The preliminary results indicated that dissolution appeared to be the most important taphonomic process affecting freshwater shells, and its magnitude appeared to be

Figure 9 Shell preservation in Holocene alluvial successions from central-western Argentina. (a–c) *Chilina mendozana* showing different degrees of breakage and dissolution; (d) *Biomphalaria peregrina* showing incipient dissolution.

quantitatively similar to those recorded in marine assemblages. As the great majority of shells were preserved within the living habitat, these assemblages also preserved good spatial fidelity.

Conclusions

The high abundance, diversity, and relative size exhibited by freshwater mollusks make them a very valuable proxy for paleolimnological and taphonomic studies. The relatively large shell size (compared to that of microfossils) allows easy recognition of any alteration in shell texture by taphonomic processes, which is of relevance for outlining the origin of fossil deposits as well as for understanding the processes of fossilization in freshwater. From preliminary taphonomic studies, it can be determined whether there is high taxonomic and ecological fidelity in a freshwater habitat. Mollusk death assemblages preserved in the littoral zone of freshwater bodies appear to be good indicators of the degree of biocoenosis, which confirms the utility of freshwater fossil shells as paleolimnological indicators. Thus, it becomes very important to include some cores from near shore sites when sampling lakes (paleolimnological studies usually involve only cores from the deepest point of the lakes). In addition, the carbonate shell allows very precise paleoclimatic reconstructions (mainly temperature and related hydrological processes) through the analysis of the oxygen stable isotope composition. Micromilling of accretionary shell carbonate yields ontogenetic variation in $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values that can be used to characterize the environment and physiology of the CaCO_3 secreting organism at high resolution.

There are several questions to be addressed in order to define paleolimnological reconstructions from freshwater mollusks. For instance, the scale of time averaging (the amount of time represented within fossil assemblages) is still unknown for freshwater habitats. Cohen (1989) estimated a value >2000 years for modern death assemblages of Lake Tanganyika (Africa). There is a huge need to increase the number of

actualistic taphonomic studies in different continental settings, in order to know how patterns and processes vary at local and regional scales. It is also very important to combine contemporary ecology and paleoecology to gain a fuller understanding of changing ecological patterns at multiple timescales. At present, it can be said that our knowledge on paleoecological and taphonomic aspects of Quaternary freshwater mollusks is at an early stage of development, with preliminary results showing great potential for future research directions.

Acknowledgements

The author is grateful to Marianne Douglas for inviting him to contribute to this publication, as well as to Kate Mittell (development editor) and Scott Elias (editor-in-chief) for their excellent work in editing the manuscript, which improved the quality of the article greatly. He is also indebted to María de los Angeles González Sagrario for helping in the compilation of the bibliography. Sergio Martínez, Christopher Wurster, and Monica Carroll provided high-quality illustrations of their original figures. Gabriela Hassan made important comments on an earlier version of the manuscript. Arthur Bogan kindly assisted with bivalve taxonomy. The author is a member of Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET).

Introduction

In recent decades, paleolimnological reconstructions of long-term changes in lake water chemistry have proven to be valuable contributors to the resolution of scientific problems, many of which are at the forefront of public debates regarding environmental management. Paleolimnological techniques have been effective in reconstructing past changes in water chemistry variables because these methods rely on biota and on geochemical processes that respond in predictable ways to changes in lake water chemistry. As long-term measured data from lakes are exceedingly rare in most regions of the world, these proxy records are valuable in assessing the nature and trajectories of water chemistry changes in many freshwater systems (Smol, 2008). Paleolimnological records developed from sediment profiles can generate information about the magnitude, timing, and causes of historical changes in the water chemistry of freshwater systems. Perhaps the most valuable contribution that paleolimnological studies make is through their ability to separate long-term, naturally occurring ecosystem processes from changes related to anthropogenic activities.

Early paleolimnological studies attempted to qualitatively infer changes in water chemistry, based on biotic changes in lakes. While these studies could identify patterns of community change, and thus made important scientific contributions, they were limited by their inability to generate quantitative information. Recent refinements, particularly in the area of multivariate statistical methods and geochemical analytical techniques, have resulted in great advances in the precision, accuracy, and reliability of paleolimnological inferences drawn from the sedimentary record in modern studies. Within the last several decades, paleolimnological contributions have provided the insights needed to inform public debate about water chemistry issues with widespread impacts, most notably those surrounding eutrophication, acidification, and climate change resulting from anthropogenic activities. As paleolimnological techniques for reconstructing water chemistry continue to grow in diversity and sophistication, they will remain important contributors to scientific and public discussions regarding key societal issues.

Acidification

Background

Widespread public awareness of acid precipitation and lake acidification began in the 1970s and early 1980s when studies linked changes in lakes, particularly the loss of fish populations, to acidification in these sites and attributed these changes to industrial pollution. However, the political influence and economic clout of the industries involved in this pollution resulted in a prolonged debate about the causes of acidification and the certainty of the underlying science. A need arose for scientists to show conclusively that these lakes had been acidified by anthropogenic pollution, and

that they were neither naturally acidic nor had been acidified through natural processes. Counter arguments and denials of responsibility by industry led to additional research, and it was in these responses to industry that paleolimnology truly demonstrated the unique contributions it could make in drawing conclusions about such historical questions (reviewed in Smol, 2008).

The Effects of Acidification on Lake Ecosystems

Acidification has profound repercussions for lake ecosystems, and the changes in lake water chemistry associated with the acidification process affect aquatic organisms through both direct and indirect mechanisms. Acidification occurs due to the deposition of sulfur and nitrogen compounds from industrial activity in precipitation. In catchments receiving acidic precipitation, metals in soils (most notably Al) can be increasingly mobilized and transported into lakes, elevating concentrations in these waters. Dissolved organic carbon (DOC) concentrations in lake waters can also be greatly reduced as a result of acidification (see below). Acidification also has profound effects on lake biota and can lead to the complete alteration of lake food webs. Many of these effects were documented during whole-lake experiments in the Experimental Lakes Area in northern Ontario (Schindler et al., 1985). Acidification can cause large changes in phytoplankton communities, including reductions in the diversity of certain algal groups, and a change in the dominance of different phytoplankton and periphyton groups. Similar impacts affect aquatic plants which typically exhibit reduced diversity. In addition, acidification typically results in changes to invertebrate communities, as some invertebrate groups are unable to survive at low pH values, while those that remain may prosper due to decreased competition. Declining lake water calcium is also linked to the long-term effects of acid deposition. Paleolimnological studies have shown that the reduction of Ca concentrations below important thresholds in North American lakes has led to species replacements and indeed the disappearance of sensitive zooplankton species (Jeziorski et al., 2008). Near the top of the food web, acidification results in the disruption or cessation of reproduction among fish populations, and eventually to the extirpation of certain fish species in acidified lakes (Schindler et al., 1985).

Paleolimnological Studies of Acidification

Large-scale paleolimnological investigations were launched into the acidification of lakes in North America (Paleoecological Investigation of Recent Lake Acidification (PIRLA), Charles and Whitehead, 1986) and Europe (the Surface Water Acidification Programme (SWAP), Battarbee et al., 1990). The goals of each of these studies were to conduct regional assessments of lakes to determine the natural background pH conditions of these ecosystems and to determine whether their acidic state

resulted from natural processes, such as long-term postglacial soil acidification, soil changes due to land use or catchment vegetation changes, or if anthropogenic impacts were responsible for recent changes in the acidity of the lakes in these regions. Many of the methodologies now viewed as standard practice by paleolimnologists were developed as a result of these projects. Although these studies primarily used diatoms for reconstructions, other biological indicators were examined, and they have continued to be developed as indicators of acidity, including chrysophyte scales and cysts (Figure 1, see Smol and Cumming, 2000), chironomids and other midges, and cladocerans.

The reconstruction of acidification from microfossil groups is typically done through the application of a transfer function, which is developed using a calibration set (also called a training set) (outlined in Birks, 1998). In this approach, a series of lakes are sampled, physical and chemical measurements are taken from lake water, and modern bioindicator communities are analyzed, normally from surface sediments. Detailed datasets of these indicator groups are then compared with lake chemistry using multivariate statistics, and so-called transfer functions are developed that can generate inferences of water chemistry variables (e.g., pH, alkalinity, phosphorus) based on the analysis of microfossil communities (see Battarbee et al., 2008).

Geochemical proxies have also been used to reconstruct acidification, including measurements of total sulfur and of sulfur stable isotope changes (see Nriagu and Coker, 1983). Isotopic measurements of sulfur in these studies may additionally allow the source of sulfur pollution to be pinpointed (Nriagu and Coker, 1983). More recently, measurements of sediment copper and nickel, in addition to biological proxy indicators, have been used to track the recovery of industrially acidified lakes toward preimpact conditions (Tropea et al., 2010). Another promising geochemical technique that has recently been applied to paleolimnological problems, including acidification, is near-infrared spectroscopy (NIRS). In NIRS analyses, the properties of lake sediment samples are determined by their transmittance of radiation in the near-infrared wavelengths (700–2500 nm). The frequencies of radiation absorbed by sediments are dependent on their chemical composition, and the spectra produced by these analyses can be

used to infer the chemistry of sediments (reviewed in Korsman et al., 2001). The same training set approach used for other paleolimnological indicators (see above) must also be used to calibrate NIRS methods prior to performing quantitative reconstructions from sediment profiles. NIRS has shown great promise as a tool for developing accurate yet relatively simple and inexpensive inferences of water chemistry variables, including pH, in paleolimnological studies (Korsman et al., 2001; Rosén et al., 2011).

Changes in the pH status of lakes are not always due to anthropogenic effects. In certain cases, such as in high-altitude or high-latitude lakes, climate and related factors may exert primary control over lake acidity. Reconstructions of lake water pH can thus also be useful as indicators of climate change. Variations in pH have been shown to be linked with climate in remote, alpine lakes in Europe (Psenner and Schmidt, 1992). Diatom-based pH reconstructions have also been successful at mirroring measured climate records at time-scales from several hundred years in alpine lakes in Austria (Sommaruga-Wögrath et al., 1997) to recent decades in the Canadian High Arctic (Antoniades et al., 2005), demonstrating the potential of these techniques to utilize changes in pH to reconstruct longer term climatic change in such remote regions.

Eutrophication

Background

Nutrients, primarily phosphorus and nitrogen, play a vital role in determining the biological dynamics of a lake and are therefore of special interest to paleolimnologists and the public at large. Eutrophication, which is the process by which lakes become more productive due to increases in nutrients, can happen as a result of natural or anthropogenic causes (see Harper, 1991; Smol, 2008). Eutrophication can occur due to natural increases in the nutrient flux from several sources, as lakes receive inputs of nutrients from rivers, overland drainage in their catchments, and atmospheric deposition. These natural variations may be caused by changes in climate or changes in vegetation, among other factors. A far more common concern is cultural (i.e., human-induced) eutrophication. Cultural eutrophication is typically caused by point source pollution and may result from increases in nutrient inputs to lakes due to fertilizer runoff, untreated sewage, or industrial outputs (Harper, 1991). The deterioration of water quality in many lakes due to increased nutrients became a widely acknowledged problem in the 1960s and 1970s and continues to be among the most serious problems facing freshwater ecosystems today. Schindler (1974) convincingly showed through whole-lake manipulation experiments that phosphorus, often derived from detergents and other human sources, was responsible for this degradation.

The Consequences of Eutrophication for Lakes

The effects of eutrophication in lakes can include the development of algal blooms (including toxic forms), decreases in water clarity, increases in the growth of aquatic plants, decreases in hypolimnetic oxygen concentrations that affect fish populations, and taste and odor problems associated with

Figure 1 Stratigraphic diagram from Swan Lake, ON, Canada, showing paleolimnological reconstruction of (a) trends in pH inferred from chrysophyte scales and their agreement with measured values for lake water pH recovery and (b) how these changes reflect nearby emissions from smelting (adapted from Dixit et al., 1989).

drinking water (Figure 2, reviewed in Smol, 2008). These changes can also profoundly alter the food webs of freshwater ecosystems. Paleolimnology can play an important role in determining the timescale and magnitude of historical changes in trophic status and also in providing information on whether these changes result from natural processes or are human induced. The effects of eutrophication are pervasive in lake ecosystems; therefore, paleolimnologists have a number of options when selecting a proxy indicator for reconstructing past nutrient levels, and these can be used either independently or in complementary approaches. Because P is the most common limiting nutrient in temperate freshwater systems, it is by far the most frequent nutrient level reconstructed in paleolimnological study and will be the focus of this discussion. However, efforts to reconstruct nitrogen levels from lake sediments typically have similar strengths and limitations to those of phosphorus. Nitrogen reconstructions can be undertaken in N-limited water bodies, or in sites where nitrogen is of particular interest, using similar approaches to those described here (see Smol, 2008).

Paleolimnological Reconstructions of Lake Eutrophication

Intuitively, the simplest and most direct way to reconstruct lake P levels would be to measure the phosphorus concentrations of the sediments themselves. However, there are several

Figure 2 Algal blooms and excessive growth often result from eutrophication in freshwater sites. Top, cyanobacterial blooms on Lac St. Augustin, Québec, Canada (photograph by Martin Bouchard-Valentine). Bottom, diversion of River Cher at Chenonceaux Castle, Chenonceaux, France (photograph by R. Pienitz).

complicating factors that hinder the development of historical lake water phosphorus records from sediments. First, it is critical to identify the proportions of sedimentary phosphorus that are derived from autochthonous and allochthonous sources in order to draw any conclusions about past lake water chemistry. In addition, rates of phosphorus accumulation in lake sediments are affected by the iron content of water, and changes in redox status can affect the rates of phosphorus accumulation in sediments. Both of these processes can alter phosphorus exchange between the water column and sediments over time so that they may not consistently reflect the concentrations of lake P at the time of deposition. Also, in sites with anoxic bottom water, the net flux of phosphorus may be from the sediments to the overlying water (reviewed in Boyle, 2001). The complex nature of these depositional and diagenetic processes implies that a thorough understanding of a lake's depositional system is required, and even then, paleolimnological records of phosphorus derived from sediment measurements must be carefully interpreted.

Analysis of biogenic silica offers another geochemical approach to inferring eutrophication histories through the reconstruction past production levels of organisms with siliceous components, and so the approach is most useful for tracking past changes in diatom algal populations. Biogenic silica analysis is a measure of the concentrations of amorphous silica in sediments, which is primarily a proxy for the abundance of diatoms and other siliceous microfossils in lakes (reviewed in Conley and Schelske, 2001). Although biogenic silica analyses can only provide information regarding siliceous organisms, these inferences have been shown to be reliable reconstructions of productivity and are commonly used to infer past levels of phosphorus from sedimentary profiles.

Several different bioindicators have been successfully used to derive robust inferences of past phosphorus levels in lakes. Of these, diatoms have been by far the most commonly used microfossil group used in studies that reconstruct past lake water phosphorus (Hall and Smol, 2010). Because phosphorus is so closely tied to primary productivity in most freshwater aquatic systems, algal indicators typically respond quickly and consistently to changes in phosphorus levels, and phosphorus levels are commonly among the factors most directly linked with changing community composition. Other bioindicator communities may respond directly to changes in phosphorus, or as a result of changes in other organisms within their food webs. As such, phycological and zoological indicators have both proven effective in reconstructing lake water phosphorus. Using transfer function approaches, paleolimnologists have been successful in quantitatively reconstructing the eutrophication histories of lakes using different indicator fossils, including diatoms (see Hall and Smol, 2010), chrysophyte scales and cysts (see Zeeb and Smol, 2001), and cladocera. In addition, recent studies have shown that NIRS analyses are capable of detecting and reconstructing trophic status from measurements of bulk sediment (see discussion above, Korsman et al., 2001).

Another common effect of lake eutrophication is the development of anoxic conditions in the hypolimnion of lakes. Hypolimnetic anoxia develops from increases in the rate of bacterial decomposition of organic matter due to the higher rates of productivity and organic sedimentation that result

from eutrophic conditions. The higher consumption of oxygen near the sediment–water interface can lead to anoxia in lake bottom waters. Chironomids are particularly sensitive to this change in lake water oxygen concentration, as a large part of the life cycles of some taxa are spent in benthic habitats. Models have been developed to infer hypolimnetic oxygen status or total phosphorus from chironomid remains (e.g., Quinlan et al., 1998), and these models have been applied to sediment cores in historical reconstructions of hypolimnetic oxygen and eutrophication (see reviews in Porinchu and MacDonald, 2003).

Fossil pigments in sediment cores have also been used to reconstruct the development of eutrophication-induced anoxia. Specific marker pigments such as okenone and isorenieratene permit reconstructions of anoxic conditions because the sulfur bacteria that produce them are obligate anaerobes. The presence of such pigments has been used in paleolimnological studies to infer the development of anoxia in a lake subject to eutrophication from sewage inputs (Antoniades et al., 2011).

Salinity

Background

Records of lake water salinity and/or specific conductivity changes are of interest to paleolimnologists because these variables are typically controlled by climate. As a result, the ultimate goal of paleolimnological studies concerned with salinity is often the indirect reconstruction of climatic change (Smol and Cumming, 2000). The majority of paleosalinity studies have focused on closed-basin lakes (i.e., those without an outlet), since the cause of salinity changes in such lakes is essentially limited to the difference between precipitation and evaporation, allowing for the reconstruction of drought histories (Figure 3). These drought records are of particular interest in arid regions such as the continental interiors of North America or Australia, where frequent and/or severe droughts can have great economic consequences, as well as in the Antarctic. Salinity changes are recorded in the paleolimnological record by their effects on the community structure of bioindicators, as well as by geochemical signals left in the structure of microfossil remains.

Studies of Paleosalinity

Diatoms have also been the most commonly used paleoindicator group for inferring past salinity levels. Their species distributions have been shown to be strongly correlated with salinity in many lakes. They have therefore been successfully and extensively used as indicators of paleosalinity in numerous studies. Another algal group that has been used to reconstruct changes in salinity is fossil chrysophytes. Although chrysophyte scales can be used in such approaches, preservation problems exist in high-salinity waters. However, chrysophyte cysts can be used effectively to infer paleosalinity and are not prone to the same preservation problems (reviewed in Zeeb and Smol, 2001). Salinity changes are also reflected in chironomid communities, and transfer functions and salinity reconstructions have been completed from fossil chironomids in diverse regions including Europe, Canada, and Africa.

Figure 3 Dramatic changes in the chemistry of closed-basin lakes are preserved by multiple indicators in the paleolimnological record. Top, lake PC36, British Columbia, Canada in spring 1991 (photograph by Susan Wilson). Bottom, lake PC36 in fall 1991, showing the effects of evaporative concentration (photograph by B. Cumming).

Freshwater ostracods have also proven to be reliable indicators of paleosalinity. Past salinity levels can be derived from ostracods using two approaches (see Holmes, 2001 for a review). Ostracod community composition is sensitive to the chemical composition of saline waters as well as to any change in salinity levels. In addition, ostracod shells are secreted over very short time periods, and an analysis of trace element geochemistry, most importantly concentrations and ratios of Sr and Mg, can be used to infer salinity levels at the time of secretion (Chivas et al., 1985). These geochemical approaches can also be applied to fossil mollusks.

Dissolved Organic Carbon

Background

DOC is an important component of freshwaters, and it plays a central role in many limnological processes (Williamson et al., 1999). DOC is often largely derived from terrestrial vegetation (so-called allochthonous sources) and deposited from lake catchments either by streams or by overland flow (Figure 4). In some environments, however, *in situ* algal and macrophyte production can give rise to large quantities of DOC (autochthonous sources). As such, on local scales, the degree of vegetation and the moisture regimes of catchments control the supply, delivery, and thus lake water DOC concentration. On broader scales, studies suggest that lake water DOC concentration in

Figure 4 DOC attenuates UV radiation and protects organisms from its harmful effects. Left, a high DOC site, Skraeling Island, Canada (photograph by Bronwyn Keatley). Middle and right, pictures show the effects of high DOC on water color, Mould Bay, Prince Patrick Island, Canada (photographs by J. Smol).

Europe and North America increased during the late twentieth and early twenty-first centuries (Evans et al., 2005). The cause of this increase is the subject of debate, with suggested causes including climate change, deforestation, and changes in atmospheric deposition chemistry (Monteith et al., 2007; Roulet and Moore, 2006; Weyhenmeyer and Karlsson, 2009).

The Effects of Lake Water DOC Concentrations

Exposure to ultraviolet (UV) radiation (UV-A: 320–400 nm, UV-B: 280–320 nm), and especially to UV-B radiation, can produce harmful effects on lake biota (Rautio and Tartarotti, 2010; Vincent and Roy, 1993). However, DOC acts as a natural sunscreen and is a strong attenuator of UV radiation (UVR) in freshwaters. It most strongly absorbs UVR in the wavelengths that are most harmful to aquatic organisms (reviewed in Vincent and Pienitz, 1996). Although concerns exist about increased UVR exposure due to thinning of the stratospheric ozone layer, Pienitz and Vincent (2000) showed that the effects of changing lake water DOC levels on underwater UVR exposure were over 100 times greater than those caused by ozone thinning. Lakes with low levels of DOC (i.e., $<4 \text{ mg l}^{-1}$), most commonly located in sparsely vegetated regions such as at high altitudes or latitudes, are particularly transparent to UV radiation. They are thereby vulnerable to biotic damage as a result of any increase in incoming UV radiation (e.g., Laurion et al., 1997).

Paleolimnology and Reconstruction of DOC Histories

An understanding of past DOC dynamics is important to paleolimnologists (and limnologists) for two major reasons. First, because of its critical role in protecting lake biota from UV radiation, DOC histories can help to determine the vulnerability of a lake due to changes in incident UV radiation. Second, because DOC is affected by other variables of interest to paleolimnologists, including changes in acidity, vegetation, and hydrological regime, DOC changes can also be used as proxies for other influences, such as climate and pollution. Under predicted future climate change scenarios, DOC in lakes is expected to decrease in regions subject to reductions in precipitation and greater drought frequency but could also increase in the lakes of certain ecotonal regions as a result of shifting vegetation zones, such as the northward movement of treeline in subarctic regions.

There are two main approaches that paleolimnologists have successfully used to reconstruct DOC levels. In certain regions, DOC is among the strongest controlling factors influencing

diatom community compositions. The majority of such DOC reconstructions to date have focused on reconstructing the effects of treeline shifts in subarctic Canada and Russia (e.g., Pienitz and Vincent, 2000). Because of the relationship between DOC and pH, diatom-inferred DOC records have also been used as a proxy for acidification in studies of industrial pollution (Dixit et al., 2001). More recently, visible NIRS has been used to develop models to infer DOC concentrations directly from sediments (Rouillard et al., 2011).

The second major approach to reconstructing changes in historical DOC levels has been through analysis of sediments to identify and quantify fossil pigments. In such studies, measurements are taken of the abundances in sediments of various pigments produced by algae and cyanobacteria to protect themselves from UV exposure. Periods of higher exposure to UV radiation cause increases in the production of these UV-shielding pigments, and thus their concentrations in lake sediments are increased. Inferences of historical DOC levels can then be made on the basis of variations of key pigments in the sedimentary record (see also Leavitt and Hodgson, 2001).

Trace Metals

Background

Trace metals, such as copper, selenium, and zinc, are micronutrients required by biota. However, as concentrations increase, these metals can become toxic, while other heavy metals such as cadmium, mercury, lead, chromium, and thallium are toxic even at low concentrations. As is the case of almost all water chemistry variables, metal concentrations in lake water are at least partially derived from their catchments, and their natural (i.e., background) concentrations are dependent on local geology and hydrological regimes, among other factors. Inputs in lakes of trace metals resulting from anthropogenic activities can be derived from point source pollution, although deposition through the atmosphere from diffuse sources is a more common source (reviewed in Smol, 2008).

Paleolimnological Studies of Metal Concentrations

Paleolimnologists have relied primarily on geochemical analysis of bulk sediments to reconstruct changes in past concentrations of metals. Although metal concentrations in the sedimentary record may be complicated by postdepositional processes, paleolimnological studies can, at the very least, infer

trends in metal concentrations (reviewed in Boyle, 2001; Smol, 2008). The effect of metal inputs may vary between lakes, as the natural water chemistry for a site can determine the biological availability of metals and the ability of lake sediments to act as sinks for metals. Depending on the focus of scientific investigation, diverse metals have been the subject of paleolimnological study, including Pb, Hg, Cu, S, Ni, and Zn. Changes in these metals in the sedimentary record have provided evidence of the effects of local industrial or mining activity, combustion of fossil fuels, and long-range deposition (Smol, 2008). Isotopic methods using lake sediments can also be used to differentiate between natural metal deposition and anthropogenic sources and in certain cases can pinpoint the sources of pollution. Although geochemical methods have been the primary means of reconstructing metal concentrations, cladocerans, sedimentary pigments, and diatoms (through both compositional change and an increase in deformities) have also been used to infer trends in past metal concentrations (Figure 5, reviewed in Smol, 2008).

Persistent Organic Pollutants

Background

Persistent organic pollutants (POPs), including polycyclic aromatic hydrocarbons (PAHs), are a group of chemicals that share certain characteristics: they persist in the environment (from weeks to decades), they are toxic (to various levels) to organisms, and they are biomagnified through successive levels of food webs (reviewed in Blais and Muir, 2001). Many different substances with diverse uses fall within this definition, including such well-known substances as dichlorodiphenyltrichloroethane (DDT), polychlorinated biphenyls (PCBs), PAHs, and dioxins. A large number of these chemicals are human-made. Due to their persistence in the environment, POPs may be transported over long distances and therefore can be found in surprisingly high concentrations in remote lakes, biota, and sediments that are far removed from POP use (see Muir and Rose, 2004). Although POPs are often found in lakes in concentrations of parts per billion or even parts per trillion, these substances are of great concern to

ecologists and the public because they can have damaging effects on organisms at extremely low concentrations. The situation is complicated further as many POPs may be biomagnified up the food chain. Concern over the health effects of POPs has resulted in bans on the use of many of these substances. However, given their environmental persistence, paleolimnological studies can provide valuable insights into the fates of POPs subsequent to their deposition in freshwater ecosystems.

Paleolimnological Studies of POPs

Due to their often low concentrations, there are few reliable direct records of POPs in natural waters. In recent decades, improvements in analytical techniques have allowed for more reliable measurements of POPs to be made (see Blais and Muir, 2001). However, the general lack of historical measurements of POP concentrations makes information derived from paleolimnological studies particularly valuable. As with all paleolimnological techniques, an understanding of the processes involved in POP deposition is required for accurate interpretation of the sedimentary record. Although concerns also exist about diagenetic processes, indications are that the concentrations of POPs in sediments often provide important archives of past contaminant loads, although diffusion and other postdepositional processes may occur within sediments (Muir and Rose, 2004; Smol, 2008). POPs have also been observed to be removed from the water column more quickly in eutrophic lakes due to increases in both sedimentation and scavenging by phytoplankton (reviewed in Blais and Muir, 2001).

Studies using lake sediments have provided insights into the transport and fate of POPs. Such studies have demonstrated the pervasive nature of these compounds in global ecosystems, clarified the processes involved in the cycling and transportation of these substances to the polar regions (known as global distillation), and produced information about the sources of POP in lake sediments. Recent research has concentrated on wildlife populations, particularly seabirds, as 'biovectors' that can deposit contaminants in high concentrations to aquatic ecosystems (Figure 6; Blais et al., 2007). For example, it was demonstrated that northern fulmars caused greatly elevated PCB concentrations in Arctic lakes and surrounding food webs (Choy et al., 2010), and sediment core studies were used to reconstruct the historical linkages between seabird populations and contaminant deposition (Michelutti et al., 2009).

Summary

Changes in lake chemistry have profound effects on the biotic communities and environmental processes that occur within lakes. As a result, changes in lake chemistry are often preserved in the sedimentary record of these lakes. Paleolimnological proxy records, constructed using both biological and geochemical indicators, can provide important information about the histories of lakes and changes in their chemistry that could not be derived otherwise from other sources.

Figure 5 Teratogenic (deformed) diatoms (a, b, d, e) are commonly found in lakes impacted by metal pollution. Normal specimens are shown for comparison (c, f).

Figure 6 Diagram showing the flow of contaminants such as POPs and the role of wildlife as 'biovectors.' Chemicals are released from industrial or agricultural applications and pass through the atmosphere or hydrosphere where they are incorporated into food webs and biomagnified in animals. These animals then congregate in areas such as hatcheries and deposit contaminants in high concentrations. Physical Properties of Lake Sediments

Physical Properties of Lacustrine Sediments

As most Quaternary scientists use lacustrine sediments as a paleoenvironmental proxy, the focus of this article is on those physical properties of the lacustrine sedimentary record diagnostic in a proxy context. Most attention is placed here upon the sediments, with additional reference to the methods of assessing physical properties. We have also sought to catalog the data available from the literature on the physical properties of lakes for reference and comparative purposes. Despite the vast number of measurements performed to assess the physical properties of lacustrine sediment, the majority of those data are not publicly accessible; results are reported by way of summary statistics, descriptive text, or figures.

Sedimentary processes in lakes are determined by a process network within, and beyond, the lake. Since lakes can preserve near-continuous records of change, both within the lake, and the contributing watershed (Last and Smol, 2001), frequent use has been made of the physical properties of lacustrine deposits as paleoenvironmental records; such use has included varve thickness (e.g., Nederbragt and Thunrow, 2001), grain size (e.g., Sundborg and Calles, 2001), grain density (e.g., Kashiwaya et al., 1999), and mineralogy (e.g., Solotchina et al., 2004). Indeed, reliance on physical properties of sedimentary sequences as paleoenvironmental proxy records is a well-established theme in the literature; some of these records span 10^5 years (e.g., Kashiwaya et al., 1999; Vogel et al., 2010). All lacustrine sediments exhibit physical properties that are a composite product of processes occurring at a range of temporal and spatial scales. In recognition of this complexity, Hodder et al. (2007) defined the 'process network' as the system of temporally and spatially connected processes involved in the transfer of an environmental signal that is expressed in physical (or other) properties of lacustrine sediment (Figure 1). Although our emphasis is placed on physical properties, links with the geochemical and biological properties of sediments are similarly related to the process network but are omitted from Figure 1.

Although the process network can be considered conceptually identical for all lakes, the network at any one lake must be operationally unique, as no two lakes experience an identical suite of variables. Even for a single lake, the network is likely to be temporally dynamic as the various component systems evolve. That each process network is operationally unique, and temporally dynamic, is a mixed blessing in the use of lacustrine sediments and their physical properties as paleoenvironmental proxies. On the one hand, sensitivity to environmental processes is requisite, as it is vital that lacustrine sediment preserves a composite record of network interactions to enable their use as multivariate environmental proxies. On the other hand, should the causative pathways evolve over time, it is possible that unobserved processes have contributed

in unknown ways to the sedimentary record, a challenge elaborated upon elsewhere in this volume.

Basin-Wide Properties

Whole-lake patterns of lacustrine sediment accumulation are controlled by factors including the location and nature of inflow(s), Coriolis effect, wind, basin geometry, bathymetry, basin trap efficiency, and spatiotemporal evolution of these factors. The allometric properties of the resultant lacustrine sedimentary packages are fundamental physical properties and influence any paleoenvironmental interpretation derived from physical parameters.

Remote sensing techniques offer researchers the ability to assess the nature of both (1) whole-lake and (2) long-term sedimentary records, unencumbered by the practical limitations of deep and/or spatially intensive coring. In the absence of remote sensing techniques, assessment of the quantity and locations of core sampling sites is often determined by a mix of operational considerations (equipment, water depth, remoteness), cost and complexity of the intended analysis (Gilbert, 2003c). Workers seeking to core lakes can, therefore, only benefit from additional knowledge of site specifics: bathymetry, sediment distribution, sediment depth (cf. Glew et al., 2001). Remote sensing techniques have been successfully used to assess lake coring programs (e.g., Gilbert, 2003c), particularly for selecting core sites that are as historically representative as possible and/or show evidence of continuous, regular sedimentation. Remote sensing commonly involves the acoustic reflection technique, which relies on the generation of normal-incidence acoustic waves that penetrate the sediment package, paired with detection of any reflected waves generated at the sediment–water interface and at boundaries within the sediment package. Repeated generation of acoustic pulses from a transmitter along a longitudinal profile, and detection of reflected returns, can be used to generate an acoustic profile of the sub-bottom in the form of a continuous profile (Figure 2). Acoustic profiles are not geologic cross sections, as their appearance depends on the acoustic impedance of sediment packages and the variation of sound velocity in sediment. Reflection of acoustic waves from the lake floor, and from within bottom sediments, is determined primarily by thresholds in acoustic impedance. Acoustic impedance for normal-incidence waves is a function of the density of the media and therefore related to sediment–water content, porosity, organic content, and grain-size distribution. Impedance discontinuities of sufficient magnitude, encountered as sound passes through the sediment, result in reflection of a portion of wave energy, termed a reflector. Because acoustic impedance is a function of the physical characteristics of the sediment, acoustic reflectors permit visualization of the nature of the deposit and, therefore, inference of depositional processes.

Figure 1 Conceptual model of the process network contributing to the physical properties of lacustrine sediments. Modified from: Gilbert R (2003) Lacustrine sedimentation. In: Middleton GE (ed.), *Encyclopedia of Sedimentology and Sedimentary Rocks*, pp. 404–408. Dordrecht: Kluwer; and Hodder KR, Gilbert R, and Desloges J (2007) Glaciolacustrine varved sediment as an alpine hydroclimatic proxy. *Journal of Paleolimnology* 38: 365–394. Reproduced with kind permission from Springer Science+Business Media.

An important advantage of this procedure is that it provides an overview of the stratigraphy of the entire lacustrine system in a way that single or multiple cores cannot.

Remote sensing techniques have helped demonstrate that bottom sediment packages can show considerable variation in thickness (Figure 2). Focusing (Likens and Davis, 1975) of sediment in certain regions of lake basins has been attributed to the action of turbidity currents (Francus et al., 2008; Ludlam et al., 1996), slope instability (Pickrill and Irwin, 1983), the depth of overlying water (Blais and Kalff, 1995), and modification of sediment dispersal patterns by wind (Girardclos et al., 2003). The implications of sediment focusing for recovery of records of environmental change are clear: portions of the lake basin may undergo enhanced sediment accumulation, or

punctuated accumulation, and may therefore record different paleoenvironmental signals.

Lake trap efficiency describes the portion of sediment input trapped in the lake basin and therefore also the corresponding portion lost to outflow from the lake. Greater residence time of water in the basin allows for greater sediment trapping. The ratio relating lake volume to inflow (Brune, 1953) is an important property of the lake and associated sedimentary record. According to this ratio, trap efficiency will vary somewhat with inflow: the lower the volume-to-inflow ratio, the greater the susceptibility of trap efficiency to inflow variability. Thus, particularly in small basins, changes in inflow can modify the magnitude and grain-size distribution of the sediment load received at the lake floor. Where stratification restricts

Figure 2 Fence diagram of a sub-bottom acoustic record from Devil Lake, a morphologically complex basin on the Canadian Shield (45° N 76° W) showing considerable spatial variation in sediment thickness. Depths in sediment assume sound velocity as that in water: 1455 m s^{-1} . Dotted line traces bedrock surface. Acoustic facies shown are (I) late Pleistocene glaciolacustrine sediment, (II) postglacial sediment deposited during lowering of glacial Lake Iroquois, and (III) Holocene gyttja. E refers to erosion surfaces in the record; M refers to multiple reflectors from hard surfaces. Reproduced with kind permission from Springer Science+Business Media. Gilbert R (2003) Spatially irregular sedimentation in a small, morphologically complex lake: Implications for paleoenvironmental studies. *Journal of Paleolimnology* 29: 209–220. (License Number 2791480399320).

inflow mixing, trap efficiency also varies with the nature of mixing in addition to inflow rate. The paleoenvironmental consequences of varying trap efficiency are somewhat less explored but Axellson (1967) estimated that an order of magnitude increase in flow rate results in a two-thirds reduction in silt trapping (Figure 3). Under a set of simplifying assumptions, trap efficiency has been used to infer past inflow volumes using the difference in primary grain size between sampling points in the lake (Sundborg and Calles, 2001). This approach relies on assumptions around (1) the relationship between grain size and settling velocity, and (2) modification of the period available for suspended sediment settling under conditions of fluctuating inflow rate.

Appearance of the Sedimentary Record

Detailed notes on sediment stratigraphy inform subsequent interpretation of physical, chemical, and biological proxies. Cohen (2003, p. 163) reminds workers that accurate interpretation "... relies on sound core or outcrop descriptions, and interpretations using more sophisticated analytical techniques than the qualitative assessments of the human eye can go wildly astray when supporting core and outcrop observations are not available." Schnurrenburger et al. (2003) present a lake sediment classification scheme based, in part, on macroscopic classification of the freshly exposed sediment surface into

discrete lithologic units. Such units are described, as appropriate, by color, sedimentary structure, thickness, inclination, bedding planes, presence of macroscopic fossils, and notes on the degree of stratigraphic disturbance by the coring process. Similar observations can be made on the material trapped at or below the core catcher, if available, to aid interpretation of the region where the core was refused further entry into the sediment. Assessment of color is best performed on wet sediment as representing the material as it occurs *in situ* or on partially dried sediment where rapidly (slowly) drying coarse (fine) sediment leads to the greatest contrast in color and tone. This technique has been shown to be particularly effective in distinguishing clastic varves that are indistinct or poorly visible in wet sediment. In a partially dried core or section, fine sediment deposited in winter remains moist and darker, while the coarser sediment dries more quickly and appears lighter (Gilbert, 2003b). As well, changes in color during exposure to air and drying may provide important information, for example, as iron oxidizes from black in a reduced state to red in the oxidized state. The overriding goals of the core logging process are to (1) help guide the interpretation of any subsequent analysis, (2) describe the overall compositional variability present in the core to guide subsampling, and (3) to identify potential unconformities in the sedimentary record.

The color reflected from exposed sediment surfaces is ultimately a function of the geometry of the exposed surface

Figure 3 Sediment deposited in the outlet section of Lake Laitaure (Sweden), or remaining in suspension, in percentage of the amounts received at the lake delta over a 16:1 range of inflow rate. Plots based on calculations presented in Axellson (1967), and assume a water temperature of 8 °C, sediment particle density of 2.65 g cm⁻³, and that one-third of the lake volume is taking part in mixing (i.e., stratified lake). For a given grain size, a greater proportion are deposited at lower inflow rates. For a given deposit, a greater proportion is composed of coarse grains as inflow rate increases.

(roughness), water content, sediment mineralogy, and the intensity and spectrum of incident light. As a nondestructive sampling technique, description of color can be undertaken alongside logs of sediment type, structure, and bedding. The traditional reliance on qualitative comparison of samples with standardized Munsell color charts has been criticized for being time consuming and of questionable utility due to variations in the spectral response of the human eye (Kemp et al., 2001). Systematic downcore measurements of color reflectance using a spectrophotometer can provide reproducible and objective measurements that contribute to a quantitative, or semiquantitative, analysis. Recent application to lacustrine sediment includes the use of ratios in reflectance between wavelength bands (Debret et al., 2011), and narrow wavelength ranges (Wolfe et al., 2006), as proxy indicators of chlorophyll, carbonate, and iron concentrations. As freshly exposed core faces may oxidize rapidly, with a concomitant change in color, the use of a protective film during automated measurement may be necessary.

Radiography is less often used and more difficult to do than color analysis but is a nondestructive, and relatively rapid, technique applicable to whole cores. Radiography provides insights into the layering and internal structures of sediments (Kemp et al., 2001), as it can reveal stratigraphy otherwise not evident (Dean et al., 1999). Differential attenuation via absorption and scattering of x-radiation as it passes through the sediment sample is the result of variations in density, quantity (thickness), grain size, and mineralogy. The resulting radiograph, recorded via gray-scale intensity, is proportional to attenuation and must be calibrated with materials of known

and contrasting density (Principato, 2004). Reliance on radiographs obtained using conventional film has now migrated to digital x-radiographic techniques (St-Onge et al., 2007) and computed tomography (Ketcham and Carlson, 2001; Støren et al., 2010).

Sediment fabric describes the orientation and packing of sediment particles at the microscopic scale (Last, 2001). Although the paleoenvironmental importance of fabric has long been recognized, the available literature in application to lake sediments appears somewhat more modest (Last, 2001) – especially in contrast with marine sediments (Bennett et al., 1981; Hein, 1991). Nevertheless, mention of fabric continues to contribute to paleoenvironmental interpretations of lacustrine sediment sequences (Kemp et al., 2001). The orientation and packing of sediment particles are innately related to other physical parameters, including porosity, water content, strength, and bulk density. Fabric is controlled by the shape of the particles (e.g., single platy grains settling in calm water tend to accumulate horizontally) and by processes (especially currents) during deposition. However related these physical parameters are, the concept of sedimentary fabric is a distinct physical parameter, and use of the term ‘fabric’ has been invoked where ‘texture,’ ‘color,’ or ‘lithology’ is intended. Fabric naturally depends on the population characteristics of the grain size and shape being deposited, as well as the processes and rates of deposition, slope, and bed roughness. Analysis of fabric relies on high-resolution, optical or scanning electron microscopy (SEM) techniques to resolve grain-to-grain orientation, the presence and size of void space, and graded bedding (Dean et al., 1999; O’Brien and Pietraszek-Mattner, 1998). O’Brien and Pietraszek-Mattner (1998) used clay fabric to distinguish deposition as individual grains (Figure 4(a)) from suspension settling of flocculated sediment (Figure 4(b)).

Magnetic Properties

The paleomagnetic record of intensity, orientation, and polarity and the record of magnetic susceptibility (MS) of lacustrine sediments have been used to characterize the physical properties of the sediment, the processes of deposition, and the history of the deposit. Natural remnant magnetization in sediments is caused by the alignment of magnetic grains, particularly magnetite, in the Earth’s magnetic field at the time of deposition (Barendregt et al., 1998). Variation in the Earth’s magnetic field has occurred as a result of migration of the North Magnetic Pole and reversals in polarity. At any given location, the declination with respect to True North, the dip with respect to a horizontal plane (inclination), and the direction of the field are a function of these changes. Paleomagnetic records of inclination and declination have been used with some qualifications to date of lacustrine sedimentary records and thus establish the late Pleistocene and Holocene histories of lakes and their drainage basins (Carmichael et al., 1990; Mothersill, 1985, 1988) by comparison to type curves for a region (e.g., Creer and Tucholka, 1982). Assessment of correspondence between paleomagnetic records can reveal striking similarities among lakes within the same region (Figure 5). The most suitable materials are silt and clay-sized grains of magnetite free from secondary magnetization, postdepositional deformation, or weathering.

Figure 4 Fabric of (a) dispersed Pennsylvanian fireclay from a sedimentation experiment where grains accumulated horizontally ('face to face') and (b) flocculated clay formed in Pleistocene glacial Lake Albany where grains accumulate in a random ('cardhouse'; 'edge to face') arrangement. Sediments in (a) were dispersed in hexametaphosphate solution and allowed to settle for approximately 6 months. Reproduced from O'Brien NR and Pietraszek-Mattner S (1998) Origin of the fabric of laminated fine-grained glaciolacustrine deposits. *Journal of Sedimentary Research* 68: 832–840, with permission from the Society for Sedimentary Geology/SEPM.

Figure 5 Magnetic declination in sediments from Lake Ontario, Lake Erie, and Elk Lake based on the comparison made by Carmichael et al. (1990). This plot compiled from data presented in Carmichael et al. (1990; Lake Ontario), Creer and Tucholka (1982; Lake Erie), and Sprowl and Banerjee (1989; Elk Lake composite curve). No attempt has been made to account for variations in sedimentation rate.

These fine grains are more likely to be oriented by the magnetic field than by the processes of transport and deposition, particularly in comparison to larger particles.

Paleomagnetic dating may be particularly useful where organic materials for radiocarbon dating are absent or where ancient carbonate (e.g., as marl) contaminates contemporary carbon or in massive sediments in the absence of varves as an

absolute dating record (Larsen et al., 2000). Records of magnetic reversals in sediments that include a lacustrine component have been used to date much longer records, especially of glaciation, extending back to the Pliocene (Barendregt et al., 1998; Froese et al., 2000). The absence of a recognizable magnetic signal or a pattern through time has been used to indicate the presence of other processes that prevent the orientation

of particles to the magnetic field, including currents in the lake during both summer and winter deposition of varves (Gravenor and Coyle, 1985).

Measurement of MS involves subjecting the sediment to a low-intensity magnetic field. This induces a small magnetization that lasts only while the field is present (Nowaczyk, 2001). Measurement of MS produces a record of magnetic minerals (Bradshaw and Thompson, 1985) and so may be useful in establishing provenance of a deposit (Foster et al., 1998). Comparison of MS profiles allows correlation among sites in one deposit where the stratigraphy may otherwise be ambiguous (Loizeau et al., 1997; Figure 6). Because most volcanic ash is highly magnetically susceptible, MS is also an effective method of locating tephra layers or zones in sediment, particularly where they cannot be readily recognized by color or texture. MS may also serve as a surrogate for measurement of bulk density and organic carbon content of the sediment, as the more compact the sediment and the lower the carbon content, the higher the concentration of magnetically susceptible minerals. Measurement of MS can be carried out *in situ* on exposures or on whole cores in nonmetallic tubes and thus provides a rapid, inexpensive, nondestructive technique particularly suitable to preliminary assessment of a deposit (Dearing, 1999).

Grain Size

The size of a clastic sediment particle and the size distribution of a group of particles are fundamental physical properties. Grain-size distribution influences other physical properties of bulk sediment, such as surface area, shear strength, and bulk

density and therefore related parameters including porosity and water content. It is a key clue in the interpretation of sedimentary process within a lake basin, the provenance of the sediment, and ultimately, the paleoenvironmental conditions in the surrounding watershed (Last, 2001). Although considerable scatter exists in the relationship between water depth and mean grain size, the deepest portions of the basin generally show the smallest grain size (Figure 7). Grain size is a widely applied technique in the interpretation of sedimentary records from modern, or former, glacier-fed lakes dominated by clastic inputs.

Although the size of an individual grain is a clear concept for simple geometries, in practice, its determination for natural particles is not straightforward. Only a sphere can be described by a single 'size' measurement; natural grains vary in geometry, roughness, and volume. To some degree, the size and distribution of grains in a particular sample depend on the technique used, because the size of individual grains is defined differently in each technique. The consequence is that different techniques of analysis can produce different measures of grain size for the same sediment sample (Goossens, 2008). Such techniques include analysis by pipette, laser diffraction, image analysis, electrical sensing, and x-ray absorption during sedimentation (an extensive review of techniques is provided in Last, 2001).

Grain-size analysis is traditionally directed at characterization of discrete clastic grains that require chemical dispersion to be analyzed as individuals, termed 'primary particles.' However, natural particles are more likely to be composites including two or more primary particles associated by flocculation or aggregation. Therefore, the *in situ* or effective grain-size

Figure 6 Magnetic susceptibility of three cores from Phewa Tal, Nepal, illustrating the interpreted correlation of deposits between sites (dotted lines). Sediment stratigraphy among cores from this lake has been described as 'poorly correlated' and 'ambiguous' by Ross and Gilbert (1999). Data reinterpreted from Ross and Gilbert (1999) and permission kindly provided by Elsevier.

Figure 7 Mean grain-size relationship with relative water depth. Relative water depth (=100% for maximum depth) is used here to facilitate interlake comparison. Glacier-fed lakes are presented with solid filled symbols. This plot compiled from data presented in Schiefer (2006; Green Lake), Cahill (1981, Lake Michigan), and Hodder et al. (2006; Mud Lake). A larger mean grain size is generally found in shallow water.

distribution of the composite particles differs from the absolute grain-size distribution of the primary particles. The *in situ* hydrodynamics of the particle depend on the effective particle size, which may remain unknown, following laboratory treatments directed at characterization of primary particles. Field techniques that permit quantification of *in situ* grain size include laser diffraction (Hodder, 2009) and cameras (Grossart and Simon, 1993).

Attempts to interpret the processes that produce a particular sample are often based on suites of statistical measures of varying complexity. Size distribution is used to infer sediment deposition process, especially in comparison with other size distributions, to reveal time-transgressive trends. Unimodal distributions are rare because most deposits are the product of multiple simultaneous agents that confound a single process interpretation. Nevertheless, given a priori knowledge of the general depositional environment, the interpretation of lacustrine grain-size distributions is eased to some extent. The production, transport, and storage of sediment through the process network lead to partitioning of grain sizes within deposits from differing sedimentary environments. Lakes can usually be considered 'ultimate deposits' (cf. Stravers et al., 1991) as they undergo net deposition, and the sediment package is largely stable over the Holocene. As ultimate deposits, lakes are dominated by a background of silt and clay particles punctuated by event layers with markedly different grain-size distribution. Events interpreted from grain-size distributions in sedimentary records include turbidity currents (Gilbert et al., 2006), mass movements (Vogel et al., 2010), hurricanes (Donnelly and Woodruff, 2007), ice rafting (Vogel et al., 2010) or accumulation on lake ice platforms by niveo-eolian processes (Lewis et al., 2002), and snow avalanches (Vasskog et al., 2011).

Bulk Density

Bulk density describes the total volume of sediment relative to the dry or wet mass and therefore represents an index of the mineral, organic, gas, and water contributions within a sample. Bulk density also varies with fabric, as the grain-size distribution within a sediment sample modifies the packing of particles per unit volume. Considerable scatter may be present in the relationship between grain-size distribution and dry bulk density (Figure 8), but it is generally found that fine silt correlates strongly with dry bulk density. When used in combination with measurements of area, such as the surface area of a core sample, bulk density is a crucial physical parameter in the calculation of accumulation rates. Bulk density has also been directly applied as a proxy indicator, such as for the area covered by glacier ice (Bakke et al., 2005).

As organic material contains a significant quantity of water and in some lake sediments occupies a relatively minor volume, its specific contribution to bulk density is often omitted. In the absence of organic material, the wet bulk density (ρ_{bw}) of lake sediment can be calculated as

$$\rho_{bw} = \frac{m_w + m_s}{V_t} = \rho_w \frac{W}{100} + \rho_s \left[1 - \frac{W}{100} \right] \quad [1]$$

and is derived mass of water (m_w), mass of sediment (m_s), volume of the raw sediment sample (V_t), water content (W), density of water (ρ_w), and density of sediment particles (ρ_s). The equation assumes uniform density of sediment particles, and a value of 2.65 g cm^{-3} is typically invoked. The contributions via dissolved salts to the density of pore water are omitted. Dry bulk density (ρ_{bd}) is described by omitting the first term, assuming no water remains in pore spaces. The

Figure 8 Scatterplot matrix showing the relationship between grain size and dry bulk density (DBD; g cm^{-3}) in two Norwegian lakes: Folgefonna and Aspvatnet. Grain-size analysis using SediGraph 5100. This plot is compiled from data presented in Bakke et al. (2006a; Folgefonna; hollow symbols) and Bakke et al. (2006b; Aspvatnet; filled symbols).

density of particles is overestimated in the presence of organic material, for which wet density values between 1.0 and 1.5 g cm^{-3} are typically invoked. Dewatering of organic matter and water-bearing minerals and loss of volatile organics during the drying process may be erroneously interpreted as water lost from pore spaces. In the presence of organic material, the wet bulk density (ρ_w) of lake sediment can be calculated as

$$\rho_{bw} = \frac{m_w + m_s + m_o}{V_t} \quad [2]$$

which includes mass of water (m_w), mass of sediment (m_s), mass of organic material (m_o), and total volume of the raw sediment sample (V_t).

Water Content

Water trapped within lacustrine sediment occupies the void space between solid mineral or organic material, and measures of water content (W) are derived using the mass of a raw sediment sample (m_r) compared to the dry mass of the same sediment sample (m_d):

$$W = 100 \left[\frac{m_r - m_d}{m_r} \right] \quad [3]$$

The resulting measure of water content is a percentage by mass of the raw sample. Dried sediment samples are typically

oven dried (105°C) for 12–24 h (Heiri et al., 2001) or freeze dried, in both cases for a period sufficient to arrive at constant dry mass. This technique does not partition the source of water lost during drying, such as evaporation from pore spaces, dewatering of minerals, or dehydration of organic matter (Santisteban et al., 2004). Oven drying may also result in loss of volatile organic matter components (Meyers and Teranes, 2001). Collectively, the overlap of these effects renders W a composite measure of mass loss from multiple repositories.

An overall decline in water content with depth is typical (Figure 9) as deeper sediment has been subject to greater period and mass of loading and therefore greater dewatering than sediment above. The portion of the sedimentary record near the sediment–water interface may be more liquid than solid (Glew et al., 2001), and water content can be over 50% in this zone (Figure 9). A water content of 50% does not correspond with half of the sample volume occupied by water, as water content is calculated by mass and the density difference between water and clastic sediment necessitates a corresponding water volume much greater than 50% (Figure 10). A variety of factors, including grain size (Figure 11), organic matter content, and dry sediment density, influence the water content of lacustrine sediments. Glacier-fed lakes appear to show lower water content than other lakes (Figure 9), perhaps owing to lower productivity, rock-flour sediment inputs, and/or the focusing action of turbidity currents. Strong empirical

Figure 9 Water content with depth below the sediment–water interface. Glacier-fed lakes are presented with solid filled symbols, other lakes with hollow or dotted symbols. This plot is compiled from data presented in Schiefer (2006; Green), Larsen and Chilingar (1983; ZugerSee, Constance), Håkanson and Jansson (1983; Ekoln, Ingensjön, Tröskén, Skälsjön, Hjälmaren, St. Aspen, Vänern), and unpublished data from Lillooet Lake, British Columbia. Error bars for Green Lake are single standard deviation reported by Schiefer (2006).

associations have been demonstrated between water content and grain size (Schiefer, 2006), organic content (Menounos, 1997), water depth (Håkanson, 1981), sediment depth (Håkanson, 1981; Schiefer, 2006), and varve thickness (Gälman et al., 2006), respectively. As such, water content has been proposed as a potential surrogate measure for other physical properties (Håkanson, 1977, 1981; Menounos, 1997). Given that water content can be measured more readily, and perhaps at lesser expense, than other parameters (e.g., grain-size distribution, MS), it has also been proposed as an indicator variable useful in tuning the sampling for other analyses.

The water content immediately below the sediment–water interface shows characteristic spatial patterns within a basin, although such patterns vary widely between sites depending on the chemical, physical, and biological characteristics of each lake (Figure 12). The nonglacial pattern shows low water content values in shallow-water sediments subject to wind- and inflow-induced mixing, and with associated larger mean grain size (Bengtsson and Enell, 1986; Håkanson and Jansson, 1983). More isolated, deeper waters are often described as having a smaller mean grain size and correspondingly high water content (Figure 11). The water content of bottom sediments from glacier-fed Green Lake shows an opposite pattern – sediments retrieved from shallow water exhibit the highest water content values. Both the nonglacial and glacier-fed patterns can be distinguished in Figure 12. Glacier-fed lakes are typically highly turbid, cold, and rapidly flushed systems with correspondingly low productivity (Hodder, 2009), factors that may collectively correspond with low organic content, higher bulk density, and enhanced dewatering.

Figure 10 Relationship between water content (percentage by mass of raw sample) and percent water by volume in a two-phase mixture plotted for four values of sediment particles density (ρ_s ; g cm^{-3}). Density of water (ρ_w) assumed constant at 1.0 g cm^{-3} .

Figure 11 Water content relationship with mean grain size of bottom sediment. This plot is compiled from data presented in Håkanson (1977; Lake Ekoln) and Schiefer (2006; Green Lake).

Shear Strength

A fundamental property of a sedimentary deposit is its ability to resist deformation, commonly expressed as shear strength. Shear strength is especially important in determining the processes of slope failure and sediment focusing in a lake, the generation of other gravity flow processes such as turbidity currents, the life processes of the aquatic benthos, and the stability of engineered structures resting on the lake floor. The nature and success of sediment recovery using a corer also relate to variations in shear strength with depth, as this controls the combined nature of friction along the core walls and deformation at the leading edge of the corer (Glew et al., 2001). The ensuing stick-slip entry of the corer into the sediment is the result of changes in shear strength at, or near, the base of the corer. Penetrometers, widely applied in marine settings, rely on this property to measure shear strength *in situ* (Håkanson, 1986), within core samples (Backman et al., 2005), or to assess substrate suitability for coring in the field (Spooner et al., 2004). Shear strength will vary with depth below the sediment surface, and with position within a lake basin (Figure 13).

Shear strength (τ) is described according to

$$\tau = C + (\sigma - p) \tan \phi \quad [4]$$

where C is the cohesion between particles, σ is the pressure normal to the surface, p is the excess pore-water pressure, and ϕ is the angle of internal friction between particles. Excess pore-water pressure develops as sediment consolidates and packing

Figure 12 Water content of bottom sediments plotted against overlying relative water depth at various sites within lake and reservoir basins. Relative water depth (= 100% for the maximum depth) is used here to facilitate interlake comparison. This plot is compiled from data presented in Håkanson (1981; Hjälmaren and North Vättern, dotted symbols), Blais and Kalff (1995; Massawippi, Aylmer, and Cromwell, open symbols), Abraham et al. (1999; Georgetown, Lavon, Waco, and LBJ reservoirs, gray symbols), and Schiefer (2006; Green, black symbols). Glacier-fed Green Lake presented with black-filled symbols, other lakes with hollow, dotted, or gray-filled symbols.

increases, so the volume of water-filled voids between particles decreases and pore-water exit is limited. This situation is common in rapidly deposited sediments where grains deposited almost simultaneously form an open-network architecture which may collapse under applied stress such as loading or vibration. In some cases, this raises the pore-water pressure to near or above the normal pressure due to the mass of sediment. Particularly in sand, where cohesion is near zero, and if escape of the excess pore water is blocked by impervious fine-grained sediment above, the strength of the sediment may fall to zero. Fine-grained platy sediments, for example, clay minerals, deposited in edge-to-edge contact in saline water due to van der Waals forces may also collapse due to increased pore water and pressure. This spontaneous liquefaction (Terzaghi, 1955) changes sediment under the influence of gravity to a low-viscosity fluid. As the pore water escapes, the pressure decreases sufficiently to allow the shear strength to exceed the shear stress and the sediment ceases to move. As sediment deforms, the cohesion between particles decreases as they move one against another. This decrease in strength is referred to as the sensitivity, S , of the sediment and is expressed as the measurement of the ratio of the strength of undisturbed sediment to the strength of sediment that has been mixed mechanically, or remolded. Where $4 < S < 8$, the sediment is sensitive; where $S < 16$, the sediment is said to be quick (Terzaghi, 1955).

Early Diagenesis

Diagenesis, in the context of lacustrine sediment, refers to *in situ* changes in sediment that occur following deposition. Diagenetic modification of sediment can significantly alter the sedimentary record and therefore must be assessed in any paleoenvironmental interpretation. This includes all of the chemical, physical, and biological changes to the sediment following primary deposition: compaction, bioturbation, precipitation, and dissolution. Although chemical and biological diagenetic processes are beyond the scope of this article, some biological and chemical processes can leave behind physical features. For example, the movement of animals or insects through soft sediment can also create markings that are later visible as trace fossils (*lebensspuren*); widths can range from 10^{-4} (e.g., nematodes; O'Brien and Pietraszek-Mattner, 1998) to 10^{-2} m (e.g., water beetles; Uchman et al., 2009). Compaction occurs where sediment volume is reduced as individual grains are brought closer together, particularly where sediment is deposited rapidly. The spontaneous adjustment between sediment grains via compaction is promoted by the continued and progressive loading of overlying sediment through time. Water content is often used as a proxy for compaction (Håkanson and Jansson, 1983; Menounos, 1997). Although the porosity of the sediment is the primary control on the degree of possible compaction, other factors such as grain-size distribution and particle shape can also contribute. The overall result is the same: the density of the sediment is increased while volume is reduced.

Future Research

The physical properties of all lacustrine sediments are a composite product of processes occurring at a range of temporal

Figure 13 Shear strength in Lillooet Lake sediments plotted according to depth below sediment surface and distance from the Lillooet River delta (the primary inflow to the lake). Whiskers are single standard deviation. Shear strength generally increases with depth below surface and with distance from primary inflow. Unpublished data from Lillooet Lake, British Columbia.

and spatial scales. The composite character of the sedimentary record is precisely what makes lacustrine sediment valuable as a paleoenvironmental proxy: a variety of processes, both within the drainage basin (or lake) and beyond, contribute to the record. These sediment packages are a mix of clastic particles, organic matter, water, and other constituents. Determinations of physical properties are fundamental in any attempt to interpret a deposit as a paleoenvironmental proxy. This applies, for example, to bedding thickness or bulk density in the determination of sedimentation rate(s) or to determination of basin infill patterns to contextualize sediment accumulation and therefore the type(s) of paleoenvironmental signal recorded. Recent advances have included very-high-resolution proxies (e.g., $<100 \mu\text{m}$; Cuven et al., 2011), the generation of new proxies from physical properties (Debret et al., 2011; Wolfe et al., 2006), and deeper consideration of the nature, and consequences, of spatial variability in proxy signals (e.g., Cuven et al., 2011; Stewart and Lamoureux, 2011).

Future work will undoubtedly be aimed at exploiting a fuller understanding of the link between multiple, simultaneous processes, the nature of the associated physical properties preserved in lacustrine sediments, and the interpretation of corresponding proxies. Growing recognition of site or region specificity in lacustrine proxies promises to reveal new sources of paleoenvironmental data, some of which record unique or conflicting proxy relationships. Given the significant investments of time, effort, and funding required to produce research data, we also expect to see greater participation in data archiving/sharing following future research. Such an approach promises to promote the original research that created the data but

may also lead to new collaborations between new data users and original data creators. Data sharing is somewhat more common for temporal series of physical properties (e.g., paleolimnological proxies, World Data Center for Paleoclimatology) than spatial series of similar data. In both cases, the data represent a research product that is arguably of greater value than the associated publications in which they appear.

Contributions of Paleolimnological Research to Biogeography

K A Moser, The University of Western Ontario, London, ON, Canada

Introduction

Biogeography uses the spatial and temporal distributions of organisms to address a wide range of ecological and environmental questions including the following: (1) What are the environmental variables controlling the distribution of a group of organisms? (2) Why has the composition of this community changed over time? (3) What is the impact of climate change on ecosystems? (4) How do human activities (e.g., land clearance agriculture, mining, and other industry) affect the distribution of species? (5) How do communities respond to disturbance, such as fire? (6) What causes changes in biodiversity? (7) How do species spread from one region to another and establish populations in a new area, and (8) How does the introduction of exotic species affect ecosystem functioning? The question of scale is import to biogeographers – and these problems are addressed on spatial scales ranging from microscopic to global and on temporal scales from hours to millions of years. This article will discuss several different spatial and temporal scales but will focus on local to global scales and the last 10 000 years (the Anthropocene and Holocene).

Paleolimnology uses the physical, chemical, and biological information stored in lake, reservoir, wetland, and to a lesser extent, river sediments to reconstruct past environmental conditions. Underlying paleolimnological research is the principal that, in many lake systems, sediments accumulate layer upon layer, year after year, such that younger sediments overlie older sediments. A variety of dating techniques, including ^{210}Pb and ^{14}C , are available to date sediment layers (Appleby, 2001; Björck and Wohlfarth, 2001; see [History of Dating Methods](#)). Much paleolimnological research has focused on addressing a wide spectrum of environmental change issues, which have depended on an understanding of modern biogeographic distributions of aquatic organisms to reconstruct past environmental conditions (Smol, 2008, 2010). Although in the last 20–30 years, remains from many different aquatic organisms, including ostracods, diatoms, chironomids, *Chaoborus*, cladocera, algal pigments, siliceous protozoans, and chrysophytes, have been used, this review will focus on two groups, diatoms (class Bacillariophyceae; see [Diatom Introduction](#)) and midges (families Chironomidae and Chaoboridae; see [Chironomid Overview](#)).

Diatoms are unicellular algae that are characterized by a cell wall composed of opaline silica ([Figure 1](#)). The diatom cell (frustule) is comprised of two halves (valves) that fit together like a petri dish, and are held together by siliceous bands. The opaline silica composition of the cell wall ensures that diatoms are generally well preserved in lake sediments. It has been suggested that there are at least 12 000 different diatom species (Willén, 1991), but new estimates are as great as 200 000 (Mann and Droop, 1996). Based on the size, shape, and ornamentation of the valve, diatoms can be identified to species or even subspecies level ([Figure 1](#)). Diatoms are useful

bioindicators because they occur in large numbers, making statistical analyses possible, in almost every aquatic environment where there is sufficient light for photosynthesis.

Chironomids, commonly referred to as the non-biting midges, are ubiquitous in freshwater ecosystems. Their life cycle is characterized by four stages (egg, larvae, pupae, and adult), with most of their life spent in the aquatic larval stage. Larval stages have a head capsule composed of chitin and are preserved in lake sediments. Using characteristics of the mandibles and ventromental plate, chironomids can be identified to genus or species level ([Figure 2](#)). *Chaoborus*, commonly referred to as the phantom midges, are also widespread, and because the larvae are covered by a rigid, chitinous cuticle, they are represented in lake sediments by body parts such as antennal segments, premandibular fans, and head capsule fragments, although they are most commonly represented by their often well-preserved and easily identifiable chitinous mandibles (Frey, 1964). The mandible structures are usually retained in fossil assemblages and can typically be identified to species level (Uutala and Smol, 1996). Using diatom-, chironomid- and *Chaoborus*-based research, this chapter reviews how paleolimnological research is contributing to answering biogeographic questions. The basis for some of this research is the ‘paleolimnological approach.’

Following the 1980s, when rapid advances in paleolimnological techniques occurred as a result of the ‘acid rain debate’ (see [Lake Chemistry; Multiproxy Approaches](#)), paleolimnology shifted from being largely qualitative and descriptive to quantitative and analytical (Birks, 1998). Many researchers now use a ‘paleolimnological approach’ to quantitatively infer past environmental conditions ([Figure 3](#); Cohen, 2003; Smol, 2008). This approach assumes that the modern relationships between abiotic conditions and biota remain unchanged through time. Transfer functions (i.e., mathematical relationships) relate modern community composition to abiotic conditions, and these transfer functions can then be applied to fossil assemblage data to infer past abiotic variables ([Figure 4](#)). Modern community composition data are determined from the upper 0–1 cm of lake sediments, which represents a spatially and temporally integrated sample, from a large lake training or calibration set (typically more than 50 lakes). Such samples allow for direct comparison to fossil assemblages preserved in deeper sediments. A wide range of statistical techniques have been developed to determine transfer functions (Birks, 2010; Cohen, 2003). For any given study, the selection of lakes is critical, as the calibration or training set must span a gradient of the environmental variable of interest. For example, if a researcher is interested in determining past pH, the calibration set must include lakes with a wide range of pH values. Once the biotic and abiotic data are in hand, it is critical to ensure that the diatom or chironomid distribution is, indeed, controlled by the environmental variable of interest. If it is, then species optima and tolerances of the variable of interest

Figure 1 Diatom photomicrographs illustrating the two main morphologic groups: the centrics and the pennates. The pennate diatoms are subdivided into three groups based on the presence or absence of a raphe structure, which is a slit along the long axis of the diatom from which a living diatom secretes mucilage that can be used for attachment or movement. The three groups are the following: (1) the araphids, which are diatom taxa that do not have a raphe structure; (2) the monoraphids, which are diatom taxa that have a raphe structure on one valve and not the other; and (3) the biraphids, which are diatom taxa that have a raphe structure on both valves. These photographs also illustrate the incredible diversity of diatom valve structure and ornamentation, which are used to identify diatoms to species level. Photomicrographs are taken using a Leica transmission light microscope equipped with differential interference contrast optics at 1000 $\times$.

can be determined, which is an important contribution to the understanding of the biogeography of these organisms. Transfer functions have been developed to quantitatively infer pH, salinity, nutrient levels, dissolved organic carbon (DOC), metals, light, temperature, and lake level variation from diatoms (Moser, 2004; Smol and Stoermer, 2010), and temperature, lake level, salinity, phosphorus, and dissolved oxygen from chironomids (Brodersen and Quinlan, 2006; Brooks, 2006; Porinchu and MacDonald, 2003). These models have been applied to fossil assemblages to address a broad spectrum of research in biogeography including the following: (1) climate change,

(2) effects of disturbance and ensuing succession, (3) impacts of atmospheric pollution on water quality, (4) biodiversity, (5) invasive species, and (6) species extinction and evolution.

Critical to the ability to apply paleolimnological techniques to address many biogeographic issues has been the advancement of new statistical techniques, which have allowed for improved accuracy and precision in inferences of past environmental conditions (Birks, 1998). The ability to obtain high-temporal resolution records has also allowed paleolimnologists to address questions that they could not have attempted in the past. New methods for coring and subsampling sediment cores at finer intervals (Glew et al., 2001; Leroy and Colman, 2001), as well as improved dating methods (Last and Smol, 2001), have allowed researchers to infer changes over higher resolution intervals. In some cases, when annual laminations or varves are present, it is also possible to use calibration-in-time instead of calibration-in-space methods to quantitatively infer past variables, such as temperature (Larocque-Tobler et al., 2011).

Paleoclimate

Given the present period of rapid climate change, long-term (hundreds to thousands of years), high-temporal resolution (annual to centennial), quantitative records of climate are required to determine natural variability and trends in climate. Such records will help to test climate models and better predict future climate scenarios. There is also an increasing need to understand the impact of climate warming on aquatic systems in order to better predict changes to water resources.

Biogeographers have traditionally used the strong links between vegetation and climate to infer past climates, using tree rings and fossil pollen. In the last few decades, paleolimnological proxies, including diatoms and chironomids, have provided new opportunities to reconstruct paleoclimates and the impacts of climate change on aquatic systems. Inference models for temperature have been developed from diatoms (Bloom et al., 2003; Lotter et al., 1997) and chironomids (Luoto, 2009; Walker and Cwynar, 2006). However, it has been suggested that chironomid-inference models are more accurate than diatom-based models (Battarbee, 2000; Bloom et al., 2003). The reconstruction of past temperatures (both air and water) from subfossil chironomid assemblages has contributed to our understanding of past climate change, which should help us to more accurately predict the future.

One of the most studied and debated climate periods of the Quaternary is the Younger Dryas oscillation, a cold period that occurred ~13–11.5 calendar ka and punctuated a general warming trend that began at the end of the last glaciation (Broecker et al., 2010). The Younger Dryas was first reported from the North Atlantic and was hypothesized to be the result of cold glacier meltwater slowing oceanic circulation (Broecker et al., 1989). Regional temperature records of the Younger Dryas interval based on chironomid-inference models for temperature and other proxies help us understand whether changes in the North Atlantic were globally teleconnected. For example, chironomid records show that California was 4 °C colder than immediately prior to the YD and that this cold period was followed by rapid warming (Figure 5; MacDonald et al., 2008). Based on these data, a teleconnection was

Figure 2 Chironomid photomicrographs illustrating different ventromental plate and mandibular structures of subfossil chironomid remains recovered from the Sierra Nevada, United States. VMP, ventromental plate. (a) *Tanytarsina* (Chironominae: Tanytarsini) has an elongate bar or sausage-shaped, striated VMP and a flat mentum with one median tooth and five lateral teeth. (b) *Psectrocladius* (*Psectrocladius*) *sordidellus*-type (Orthoclaudiinae) has a reduced, unstriated VMP, with beard present and a strongly arched mentum with two median teeth and five lateral teeth. (c) *Microtendipes* (Chironominae: Chironomini) has a striated, fan-shaped VMP and a weakly pigmented tridentate median tooth and six lateral teeth with first tooth fused to second lateral. (d) *Dicrotendipes nervosus*-type (Chironominae: Chironomini), has a striated, fan-shaped VMP with crenulate outer margin and one median tooth and six lateral teeth with the first lateral tooth larger than the rest. (e) *Heterotrissocadius marcidus*-type (Orthoclaudiinae) has a bulbous VMP and paired median teeth with a heavily pigmented gula. Photomicrographs are taken using a Nikon transmission light microscope at 20 $\times$. Scale bar = 100 μ m. Photo credit: D.F. Porinchu.

suggested between the Atlantic and Pacific oceans. Chironomid and pollen records from Chile support this idea (Massaferro et al., 2009). However, chironomid-based temperature records from other parts of the world (e.g., Tasmania, Australia, and Yukon, Canada) indicate no temperature change during this period (Kurek et al., 2009; Rees and Cwynar, 2010). By developing a global network of sites that investigate temperature variations during this important time period and others of similar importance, it is possible to gain insights into the mechanisms driving these rapid climate change events and their translation across the globe.

Although diatoms have been used less frequently than chironomids to determine past records of temperature, diatom-based research provides striking evidence of the impacts of recent warming on aquatic systems. Research from the Arctic

has shown dramatic increases in diatom diversity (Figure 6; Douglas et al., 1994; Smol et al., 2005) that are unprecedented for at least the last 200 000 years (Axford et al., 2009). Evidence clearly links these changes to recent warming (Smol, 2010). In lakes from the boreal forest, there are coincident changes in diatom community composition, which are related to the effects of warming temperatures on ice cover, growing seasonal and thermal stratification, and the internal cycling of nutrients (Rühland and Smol, 2003). In a study from Europe, Clarke et al. used a top-bottom approach to determine changes in many lakes in response to recent warming (Clarke et al., 2005). The top-bottom approach compares a single modern sample (top 0–1 cm of sediment) to a sample representing pre-1850 (single bottom sample, usually determined to be pre-1850 using ^{210}Pb dating), allowing many lakes to be evaluated

Figure 3 The paleolimnological approach. (1) Lake sediments provide a holistic record of environmental change because they receive inputs from atmospheric, aquatic, and terrestrial systems. The sediments are laid down year after year and can be dated using a variety of dating techniques. (2) Past environmental variables can be estimated using the modern relationships between species assemblages and environmental variables from a suite of lakes, called a calibration or lake training set. (3) To determine a modern diatom assemblage, the upper 0–1 cm of sediment is collected using a gravity corer. This sediment sample represents a spatially and temporally integrated sample of the last few years. These samples are processed following standard techniques and the proxies are identified and enumerated. Information is noted about each lake, including morphometry, Secchi disc depth, temperature, pH, conductivity, and numerous other water variables (e.g., nutrients, metals, ions, etc.). (5) Records of environmental change are retrieved from a subset of lakes. A variety of different coring techniques are available and selected depending on the sediment characteristics and lake depth. These cores are subsampled and proxies are enumerated in the same manner as for the sediment surface samples. (6) Numerical analyses are used to study relationships between the modern proxies (3) and environmental data (4) in order to develop transfer functions (Figure 4) to quantitatively infer past environmental variables from fossil data (5). (7) Environmental variables can be inferred for thousands of years in the past and plotted to show past environmental change. Reproduced from Moser KA (2004) Paleolimnology and the frontiers of biogeography. *Physical Geography* 25: 453–480.

quickly. Clarke et al.'s (2005) research showed that modern day diatom community composition had changed markedly from pre-industrial communities. They analyzed diatoms in over 209 lakes from 11 different districts and found that the ratio of planktonic to benthic diatoms had increased in 7 of the 12 districts. They hypothesized that these changes were the result of temperature-related changes in nutrients, ice cover, and erosion (Figure 7). More recently, Rühland et al. (2008)

combined data from several data sets and demonstrated that changes in diatom community composition in response to recent warming may be global in scale.

In closed lake systems, increased aridity results in lower lake levels and increased salinity, which affect diatom community composition (see [Salinity and Climate Reconstructions from Continental Lakes](#)). Therefore, diatom-inference models for salinity and salinity-related variables (Fritz et al., 2010) and

lake depth (Wolin and Stone, 2010) have been used to infer past drought. On the Great Plains, paleolimnological research has indicated that during the last two millennia, droughts were much more severe than the worst droughts experienced during the historical record (Laird et al., 1996). Even longer records, spanning the entire Holocene, show that the early to mid-Holocene intervals were even drier than the last 2000–3000 years (Clark et al., 2002; Laird et al., 1996). This research shows that records spanning the last century are too short to

accurately represent the full range of the natural variability of drought on the Great Plains and thus are inadequate for reconstructing drought severity during the past, or for predicting the future (Clark et al., 2002).

Similar approaches are now being used in alpine areas of the southwestern United States (Bloom et al., 2003). Here, changes in lake depth and salinity follow steep elevational gradients, and lake calibration sets from across these gradients have provided data to develop diatom-inference models. These models, applied to fossil diatom assemblages from the Younger Dryas chronozone, show marked changes in effective moisture (precipitation minus evaporation) during this period of rapid temperature change (Figure 5; MacDonald et al., 2008). This research indicates that the Younger Dryas was not only a period of rapid temperature variability but was also marked by hydrologic change.

Finally, as dating techniques (e.g., amino acid racemization, U-series dating) are developed for the period not covered by ^{14}C dating (prior to 40 000 years ago), there is great potential for determining long records (hundreds of thousands to millions of years) of regional climate change from ancient lakes. For example, records from Bear Lake, Utah (USA; Kaufman et al., 2009) and Lake Ohrid (Macedonia/Albania) (Reed et al., 2010), used diatoms and other proxies to determine regional climate change and link these regional records to global records of glacial–interglacial cycles. Such records provide data critical for understanding global climate connections past and future.

Figure 4 Schematic diagram showing that a transfer function is a mathematical relationship established between modern species (calibration data set) and environmental data (associated environmental variables). This mathematical relationship can then be applied to fossil data (downcore data) to infer past environmental variables (paleoecological estimates). Reproduced from Bradley RS (1983) *Paleoclimatology: Reconstructing Climates of the Quaternary*. San Diego: Harcourt-Academic Press.

Terrestrial–Aquatic Links: Disturbance and Succession

In recent years, with the recognition of the profound impact of human activities on biogeochemical cycles (Schlesinger,

Figure 5 Graphic representing climate changes during the Younger Dryas chronozone determined from Sierra Nevada lake sediments. Chironomid-inferred temperatures for two lakes, Barrett and Starkweather, are compared to oxygen isotope-derived temperature records from GISP II (Greenland) ice cores (Alley, 2000) and sea surface temperature inferred from ODP CORE 1019 C off the coast of northern California (Barron et al., 2003). Diatom-inferred salinity from Starkweather Lake, which tracks changes in effective moisture (precipitation–evaporation), shows that the Younger Dryas was characterized by first wet and then dry conditions. This is corroborated by the cellulose $\delta^{18}\text{O}$, also from Starkweather Lake, and $\delta^{18}\text{O}$ and TIC from nearby Owens Lake (Benson et al., 1997, 2002). The shaded band shows the timing of the Younger Dryas chronozone. Reproduced from MacDonald GM, Moser KA, Bloom AM, et al. (2008) Evidence of temperature depression and hydrological variations in the eastern Sierra Nevada during the Younger Dryas stage. *Quaternary Research* 70: 131–140.

Figure 6 Photomicrographs showing recent, marked changes in diatom biodiversity, typical of arctic lakes. (a) Represents modern, diverse diatom assemblages and (b) Represents nearly monospecific communities typical of pre-1850 assemblages. This change is caused by recent and rapidly warming temperatures, which are resulting in shorter ice cover duration and greater habitat availability (Douglas et al., 1994).

1997), there has been increased interest in the development of a better understanding of the flux of chemicals between the terrestrial, aquatic, and atmospheric systems. One way that humans are altering biogeochemical cycles is through landscape change, but dramatic landscape change can also occur due to natural phenomena such as climate change, fire, disease, wind, and flooding. Natural and anthropogenic landscape changes may result in a transfer of nutrients and sediments from the terrestrial to aquatic systems, potentially altering these ecosystems. Biogeographic research has determined vegetation succession following natural disturbances and human-caused landscape change and paleolimnology provides the opportunity to determine the effects of vegetation and soil succession on aquatic systems.

Early biogeographic research hypothesized that after a disturbance, vegetation succession followed predictable, unidirectional pathways and that the vegetation of earlier stages altered the environment to allow for the establishment of subsequent vegetation (Clements, 1936). Similarly, aquatic succession was suggested to follow a unidirectional pathway of increasing eutrophication and eventual infilling of lakes and ponds with sediments (Deevey, 1942; Rohde, 1969). Recent research from Glacier Bay, Alaska (USA), used paleolimnological methods to show that this model of aquatic succession is oversimplistic, and that aquatic succession can follow many different pathways (Engstrom et al., 2000). Using fossil diatoms and a chronostratigraphic approach to follow lake development after deglaciation, Engstrom et al. (2000) found that lakes became more dilute and acidic over time, accumulated DOC, and sometimes showed a relatively early, short-term rise in nitrogen. The inferred limnological changes were largely

attributed to vegetation and soil succession, but differences in each lake's trajectory were attributed to differences in hydrology.

The Glacier Bay research examined successional changes following deglaciation; however, soil and vegetation succession also follow other natural disturbances, including, fire, windstorms, and outbreaks of pathogens. Such catchment changes are hypothesized to impact limnological conditions through changes in geochemical pathways. For example, deforestation can have a pronounced effect on a lake ecosystem through increasing runoff from the catchment that is enriched in dissolved nutrients and particulate matter (Likens, 1985). Paleolimnological research has determined a wide range of lake responses to vegetation succession. Hall and Smol (1993) showed that the rapid demise of hemlock ~4800 ¹⁴C years BP in eastern North America resulted in a minor increase in lake trophic status. Some investigators have reported an increase in nutrient export to lakes following fires (Enache and Prairie, 2000; Wright, 1976), whereas other researchers have observed no change in nutrient inputs (Paterson et al., 1998). Paleolimnological studies have also indicated reductions in lake water acidity due to increased erosion and export of base cations from the catchment (Korhola et al., 1996; Rhodes and Davis, 1995). Undoubtedly, the different lake responses that have been observed are related to the initial conditions of the lake, including the catchment characteristics and the lake chemistry, as well as the severity of the fire. Studies of the natural links between aquatic and terrestrial systems provide a context for understanding the impacts of human-caused landscape change on lake ecosystems.

In Europe, the landscape has been modified and shaped for thousands of years by human activities, including forest clearance and agriculture (Birks, 1988). Land use change can directly affect lake water quality through modification of the hydrology, nutrient loading, and increased export of other material from the catchment (Dillon and Kircher, 1975; Harper and Stewart, 1987). Similar to investigations of natural deforestation, research shows a wide range of lake responses to human deforestation. For example, in Switzerland, Lotter (2001) used pollen to show that major land clearance occurred around Soppensee during the Bronze and Iron Age, although, a diatom-inferred TP reconstruction indicated that nutrient enrichment only occurred within the last 50 years. At Diss Mere, England, however, nutrient enrichment inferred from diatoms was linked to Neolithic, Bronze Age, and Iron Age forest clearance (Birks et al., 1995). The impact of land use change will depend on the extent of deforestation, grazing pressure, tillage, and fertilizer use, as well as the starting conditions of the lake itself (Heathwaite, 1997).

In North America, research has tended to focus on the impacts of land clearance by Europeans; however, pre-European communities also altered the landscape and, in turn, water quality. For example, in southern Ontario, land clearance by the Iroquois for settlement and agriculture between AD 1268 and 1486 led to an increase in nutrient inputs, which fundamentally and permanently altered lake ecosystems from natural baseline conditions (Figure 8; Ekdahl et al., 2007). This research indicates that initial perturbations by humans may significantly affect how a lake recovers from subsequent disturbance, which has important implications for water management,

Figure 7 Map showing changes in the ratio of planktonic to benthic diatoms in 11 lake districts from across Europe. Note that the largest positive changes are reported from alpine lakes. Reproduced from Clarke G, Kernan M, Marchetto A, Sorvari S, and Catalan J (2005) Using diatoms to assess geographical patterns of change in high-altitude European lakes from pre-industrial times to the present day. *Aquatic Sciences* 67: 224–236.

particularly where prehistoric populations were larger and people less nomadic.

Owing to lower population densities of early peoples, the magnitude of change in water quality caused by landscape changes is generally much less than that caused by recent humans. Changes in diatom community composition show dramatic increases in nutrient inputs to lakes resulting from human activities, including deforestation, land clearance and agriculture, road construction, and urbanization (Smol, 2008). In some studies, changes in chironomid community composition have also shown a concomitant decrease in oxygen following increased nutrients and algal productivity (Clerk et al., 2000; Little et al., 2000). Regional assessments of eutrophication using diatom-based approaches are also possible. In Minnesota, a diatom-based transfer function was used to infer pre-European trophic status in comparison to post-settlement trends in 55 lakes (Ramstack et al., 2004). The results indicated that 30% of urban and 30% of agricultural lakes showed a statistically significant increase in phosphorus between pre-settlement levels and 1970.

The historical perspective provided by these records has important implications for determining restoration goals. For example, in Europe, the EU Water Framework Directive

has a goal to achieve a chemical and ecological level comparable to background conditions for all surface waters by the year 2015 (Räsänen et al., 2006). Here, background conditions are considered to be those existing prior to intensive farming or forestry and before large-scale industrial disturbances, and can be determined by paleolimnological reconstructions. However, if prehistoric peoples did impact lake water quality, an earlier time period may provide a more accurate representation of baseline conditions (Bradshaw et al., 2006; Räsänen et al., 2006).

Impacts of Atmospheric Pollution on Water Quality

Pollution resulting from industrial activities has caused acid rain and increased metal and nutrient emissions to the atmosphere. For example, it has been reported that industrial emissions of Pb, Cd, and Zn exceed the flux from natural sources by factors of 18, 5, and 3, respectively, and that for As, Hg, Ni, Sb, and V, the contributions from human sources may exceed those from natural sources by 100–200% (Nriagu, 1989). Emissions of nutrients, in particular nitrogen, have also increased as a result of the production of synthetic fertilizers, fossil fuel burning, and increased cultivation of leguminous

Figure 8 Diatom-inferred total phosphorus for Crawford Lake, Milton, Ontario (Canada), based on a 64-lake calibration set from southern Ontario (Reavie and Smol, 2001). Note that phosphorus increases with the onset of agriculture by the Iroquois and never returns to pre-Iroquoian levels. The greatest increase in phosphorus, however, occurs with European settlement of the catchment. The most recent decrease in phosphorus may indicate a recovery with reforestation. Reproduced from Ekdahl EJ, Terranes JL, Wittkop CA, Stoermer, EF, Reavie ED, and Smol, JP (2007) Diatom assemblage response to Iroquoian and Euro-Canadian eutrophication of Crawford Lake, Ontario, Canada. *Journal of Paleolimnology* 37: 233–246. crops (Schlesinger, 1997). Anthropogenic production of fixed nitrogen is now creating more biologically available nitrogen than natural ecosystem processes (Hessen et al., 2009). Approximately 60% of deposited atmospheric nitrogen is from human-derived sources (Schlesinger, 1997). Biogeographers are interested in how atmospheric pollution from human activities has affected species distributions and ecosystem functioning. Using paleolimnological techniques, changes in atmospheric pollution and its impacts on ecosystems can be determined.

One of the most widely studied pollution problems in paleolimnological research has been acid rain (Battarbee et al., 2010; Smol, 2008), and it is this research that has formed the basis for paleolimnological investigations of other pollution problems (see also [Lake Chemistry](#) and [Multiproxy Approaches](#)). In the 1980s, acid rain was identified as a serious environmental problem in Europe and the United States; however, no long-term measurements were available from which to determine the impacts of acid rain on lake ecosystems. The problem of acid rain required high-quality, historical data to

determine acidification trends. Key questions that needed to be addressed were the following: (1) Were lakes acidic because of acid deposition, or were they naturally acidic? (2) Was acidification part of a natural long-term trend? (3) Which lakes were most susceptible to acidification? (4) If lakes were being acidified, then by how much? (5) Are lakes recovering from reduced acid deposition? (Smol, 2008).

However, there was little monitoring of lake water pH prior to 1980, so paleolimnology was used to provide long-term, quantitative reconstructions of lake water acidity (Battarbee et al., 1990; Charles and Whitehead, 1986). Diatom-based models were used to track changes in lake water pH in the United States, Canada, and Europe. One area of particularly intense research was Adirondack Park, in upstate New York, where many of the 3000 lakes were acidic. In the Adirondacks, paleolimnological records showed that most lakes had become more acidic beginning ca. 1900–50, coincident with increases in the deposition of strong acids, as evidenced by increases in coal and oil soot particles and polycyclic aromatic hydrocarbons, lead (Pb), and vanadium (V) (Cumming et al., 1994).

In addition, regional assessments of acidification were undertaken in Adirondack Park using the top–bottom approach (Cumming et al., 1992). Diatom-inferred pH from recent sediments was compared to pH from pre-1850 sediments from selected lakes, and the changes were mapped. The map showed that lakes that underwent the greatest changes in pH from pre-1850 to the present day were those in the southwestern part of the study area where the lakes were poorly buffered and acid deposition was greatest. In this research, paleolimnological data were also used to estimate critical load values, that is, the highest load of a substance that will not cause chemical changes resulting in long-term, harmful effects (Smol, 2008). By comparing known sulfate deposition to diatom-inferred pH, the sulfate load required to induce a change in lake water pH can be determined. Using this approach, Cumming et al. (1994) showed that many Adirondack lakes acidified with wet sulfate loads of only 5–25 kg ha⁻¹ year⁻¹, which was less than reductions proposed by legislation.

These techniques can be used to track other kinds of pollution. Alpine lakes are relatively remote and as a result are often considered to be pristine and relatively untouched by humans. Paleolimnological research has shown this perception to be largely untrue, mainly owing to the deposition of long-distance pollutants. For example, paleolimnological data have been used to track changes in metal emissions and their effects on aquatic ecosystems. Research in the Swiss Alps (Kamenik et al., 2005) and Uinta Mountains, Utah, USA (Moser et al., 2010), showed significant metal enrichment in alpine lakes related to mining, although in Europe, the increase in metals occurred during the Early Medieval period, whereas in Utah, it occurred in the mid- to late-1800s with the arrival of Europeans and onset of mining. Both of these investigations showed marked changes in diatom community composition coincident with increased Pb emissions, suggesting aquatic ecosystem change in response to metal enrichment.

Recent research in alpine areas of Colorado (USA) showed striking changes in diatom community composition, indicative of increased nutrients from the 1950s (Wolfe et al., 2001, 2003). By comparing these diatom records to nitrogen isotope records, it was argued that nutrient enrichment is occurring as a result of increased nitrogen deposition from agriculture and industry to the east of the mountains. Similar changes have now been reported from many alpine regions of North America (Holtgrieve et al., 2011).

Biodiversity

Broadly defined, biodiversity is the number, variety, and variability of living organisms. Considerable biogeographic research has been directed at understanding the spatial patterns of biodiversity, and two general categories of explanations have been proposed (MacDonald, 2003). The first category is referred to as historical theories of biodiversity, which state that modern geographical distributions are controlled by historical processes, such as allopatric speciation (i.e., formation of new species by geographic isolation) and geographic dispersal. The second category assumes that modern patterns of diversity are the result of environmental conditions and biological processes (e.g., predation, competitive exclusion, and stochastic variations). For macroorganisms, it is generally accepted that

both of these categories of processes determine species distributions and diversity (Cox and Moore, 2005). However, for microorganisms there is considerable debate. It has been argued that microorganisms have cosmopolitan distributions because they are so abundant and easily dispersed that biodiversity is only limited by species environmental tolerances (Finlay, 2002). This theory is referred to as the ubiquity hypothesis (i.e., ‘everything is everywhere’ and ‘the environment selects’; Finlay, 2002). If this hypothesis is correct, biogeographic patterns (e.g., latitudinal diversity gradients) would be absent (Vyverman et al., 2007). Other research, however, indicates that microorganism, particularly diatom, distributions show biogeographic patterns similar to macroorganism distributions, indicating that historical processes are important (Martiny et al., 2006). Recently, paleolimnological research has been contributing to this debate, and results support that historical processes are important (Vanormelingen et al., 2008).

First, lake calibration or training sets developed for determining relations between diatom community composition and environmental variables provide an excellent opportunity to establish global and regional patterns of species distributions and diversity to test the ubiquity theory (Telford et al., 2006; Vyverman et al., 2007). By combining several lake training sets to develop a global lake training set, Vyverman et al. (2007) showed that variation in both regional and global genus richness was more strongly influenced by geographic variables such as connectivity between lakes, degree of lake district isolation, and habitat availability than by local environmental variables, such as pH and conductivity, implying that historical processes are important in determining diatom distributions.

Secondly, paleolimnology can be used to track the introductions of exotic species by humans, which further provides strong evidence that natural dispersal of diatom species is limited by geographic barriers. Documentary evidence of diatom introductions is rare; however, the paleolimnological record provides an opportunity to determine the history of species introductions and occurrences (Willis and Birks, 2006). For example, sediment records in New Zealand showed that prior to 1880, *Asterionella formosa*, a widespread, planktonic diatom, was absent (Vanormelingen et al., 2008). Today, this diatom is widespread, occurring in 45% of lakes with known phytoplankton records and it is suspected that this diatom arrived in New Zealand with the introduction of salmon ova. These results show that there were barriers to the expansion of *A. formosa* to New Zealand, and it was only when its dispersal was facilitated by humans that its range expanded.

Invasive Species

Biogeographers are interested in changes in species ranges, and dispersal and establishment are important controls on a species distribution. As more and more humans have traveled greater and greater distances, humans have become increasingly important vectors of dispersal of both micro- and macroorganisms. The introduction of exotic species by humans has been both purposeful and accidental, but regardless, the introduction of non-native species can have devastating impacts on ecosystems, economy, and human health (Vitousek et al.,

1997). Paleolimnology can provide a long-term context to evaluate the consequences of species introductions.

The Great Lakes, which has been referred to as an 'underwater zoo,' provides many examples of species invasions (Smol, 2008). At least 139 species have been introduced to the Great Lakes since the 1800s, of these 24 were algal species and of these 16 were diatom taxa (Mills et al., 1993). Probably all of the diatom species were introduced from Europe or Eurasia through ship ballast waters (Mills et al., 1993). Owing to limitations in monitoring the expansive Great Lakes, our capacity to track the arrival and proliferation of exotic species is quite restricted (Edlund et al., 2000).

Paleolimnological techniques provide opportunities to determine the timing and spread of invasive species and to understand their repercussions. Stoermer et al. (1985) used a dated sediment core from Lake Ontario to track the arrival and expansion of the diatom *Stephanodiscus binderanus*. This research showed that this species arrived in the Great Lakes in 1952, and Reavie et al. (1998) found a peak in this diatom correlating to the 1950s in sediment cores from the St. Lawrence River. This timing is similar to observations from Montreal (Brunel, 1956) and Chicago (Vaughn, 1961). More recently, Edlund et al. (2000) showed that the exotic diatom, *Thalassiosira baltica*, was present in Lake Ontario by 1988, even though it was not reported until 2000. In 1993, mandatory ballast water exchange, which was thought to greatly decrease the introduction of invasive species, was implemented. Because the 'observational' arrival date of 2000 occurs after 1993, the reported entry of *T. baltica* could have been used as evidence that the ballast water exchange is ineffective; however, the paleolimnological data shows that it arrived prior to mandatory ballast exchange, negating this suggestion (Smol, 2008).

Although humans have inadvertently introduced many taxa, they have also purposely introduced certain species. In freshwaters, this has typically been fish, and although fish in lakes may always seem beneficial, adding fish to naturally 'fishless' lakes alters food webs and communities that have developed over thousands of years; however, the practice of fish stocking remains widespread. It is estimated that nonnative species have been introduced in 60% of all western US mountain lakes since intensive stocking of sport fishes began in the mid-1800s (Bahls, 1992). In the Canadian Rocky Mountains, nonnative trout have been introduced to at least 20% of all lakes (Donald, 1987). Most of the time, stocking was done without collecting baseline (i.e., pre-introduction) data, and follow-up monitoring is rare (Smol, 2008). Paleolimnological data can be used to reconstruct the missing data. An example of this comes from the Canadian Rocky National Parks, where fish stocking was prevalent since the turn of the century (Lamontagne and Schindler, 1994). For present-day park managers, it was almost impossible to say whether fish communities in a lake were native, recently introduced, or a combination of the two. Three lakes in Jasper Park, which were stocked with salmonids in the 1920s and 1930s, were selected because it was unclear what their 'fish status' was prior to stocking. In order to restore the Jasper lakes, 'target conditions' were required (Smol, 2008). Using methods established in eastern North America, *Chaoborus* mandibles preserved in dated sediment cores were used to determine baseline

conditions. *Chaoborus americanus* does not survive in lakes with fish because its instars are particularly susceptible to predation by fish, and *C. trivittatus* is vulnerable to fish predation (Uutala, 1990). These two species are, therefore, indicative of 'fishless' lakes. Paleolimnological analyses of sediment cores from the three stocked Jasper lakes revealed that these two species were present in prestocking sediments from two of the lakes, indicating that these lakes were naturally fishless. This research provided park managers with critical information for successful restoration of Jasper lakes.

Extinctions and Evolution

Species evolution and extinction have occurred throughout much of Earth's history, usually at steady and gradual rates, but punctuated by periods of rapid extinction (MacDonald, 2003). Some scientists believe that the rapid rates of extinction occurring today represent a mass extinction event (Wilson, 1989). Therefore, efforts to understand factors controlling extinction and evolution are of great interest to biogeographers. Recent paleolimnological research has investigated both, but with particular attention to microorganisms.

Extinctions or extirpations (i.e., local extinctions) can occur for many reasons, including resource limitation and the introduction of exotic species. In paleolimnological research from the Great Lakes, the diatom *Stephanodiscus niagarae* was in serious decline by 1980 and had disappeared from Lake Ontario by 1988 (Julius et al., 1998). The obvious explanation for the loss of this diatom species was the continued and varied environmental stresses, including pollution and invasive species. However, a second explanation has since been suggested. By measuring valve size in sediment records, Stoermer et al. (1989) and Julius et al. (1998) showed that the mean diameter of *S. niagarae* valves began to decrease in the late 1940s to early 1950s. They hypothesized that valve size decreased owing to intense silica depletion due to increased phosphorus from pollution. Increased phosphorus led to intense diatom blooms that depleted silica resources. Eventually, diatom valve size fell below the minimum required for cells to develop.

Sediment records have also been used to study extirpations of larger organisms, such as fish. Similar to the North American Great Lakes, large lakes in Africa have recently endured multiple stresses, including human population growth, increased cultivation of land, meteorological variability, resource extraction, intensive fishing, introduction of exotic species, and more recently, climate change. In Lake Victoria, the world's largest tropical lake, almost half of its 500+ species of endemic cichlid species have gone extinct (Verschuren et al., 2002). There are two hypotheses to explain this loss. The first is that the introduction of Nile perch resulted in top-down effects to Lake Victoria's food web, which led to a loss of cichlids and increased primary productivity, and the second is that landscape change, particularly intensification of agriculture, resulted in increased productivity, which resulted in bottom-up changes (Hecky et al., 2010). The latter hypothesis argues that increased productivity led to increased inshore turbidity. Because cichlids are highly dependent on visibility for feeding and reproduction, they are less competitive in turbid waters. If the former hypothesis is correct, then primary productivity should have increased after the Nile perch populations expanded in the

1980s. Owing to a paucity of records of limnological variables for Lake Victoria, the paleolimnological record has been used to understand the loss of cichlid biodiversity. Sediment records clearly show an increase in eutrophic diatoms and increases in other measures of productivity beginning in the late 1960s. These records indicate that increased primary productivity (caused by increased phosphorus from growing populations and intensified agriculture) predates the transition to Nile perch dominance. It is, therefore, suggested that eutrophication alone can lead to extinctions and loss of biodiversity. The management implications of this research are that increasing fishing mortality of Nile perch to reverse changes in water quality will fail and the only way for any type of recovery is through decreases in phosphorus loading.

Although paleolimnological data have been used less frequently to study evolution than extinction, there is great potential for tracking evolutionary change and testing evolutionary hypotheses using lake sediment records. An example from Yellowstone Lake, Wyoming, tests the idea that large population sizes, high dispersal rates, and low reproductive barriers result in gradual rates of protist evolution (Theriot et al., 2006). *Stephanodiscus yellowstonensis*, an endemic diatom to Yellowstone Lake, was known to have evolved from *Stephanodiscus niagarae*, which does not occur in Yellowstone Lake today (Theriot, 1992). A sediment record from Yellowstone Lake revealed that dramatic morphological changes from *S. niagarae* to *S. yellowstonensis* were coincident with rapid warming and environmental change following the end of the last glaciation, as evidenced by diatom, pollen and geochemical records from the same lake sediments. These results showed that diatom evolution can occur more rapidly (one species evolved to another in ~2 ka) than previously shown and that evolutionary change in this example is directionally driven rather than random. Using similar approaches, there is great potential for addressing questions about microorganism evolution using the particularly long sediment records spanning millions of years that are preserved in ancient lakes.

Conclusion

In the past 20–30 years, paleolimnology has changed from a qualitative to a mainly quantitative science reflecting rapid technical and statistical advances. As a result, paleolimnologists have been able to effectively use fossils from diatoms, chironomids, and *Chaoborus* preserved in Quaternary lake sediments to contribute to our understanding of biogeographic issues. Using the paleolimnological approach, which uses mathematical relationships between modern assemblages and environmental variables, it has been possible to determine long-term records of temperature and drought, which provide data necessary for accurately forecasting future climate change and its impacts. Some researchers have also used paleolimnology to show how recent warming affects aquatic ecosystems around the world. Paleolimnology has furthered our understanding of the links between the terrestrial and aquatic systems and shown that previous ideas about unidirectional change and lake succession have been oversimplified. Investigators have reported the significant impact of human activities on lake water quality, both directly in the catchment and

remotely via long-distance transport of pollutants. For example, metals and nutrients derived from mining activities, agriculture, and industry are dramatically altering alpine lake ecosystems. Paleolimnological data are also being used to track the entry and spread of invasive species, which are difficult to monitor in large lake systems, such as the Great Lakes of North America and Africa. Research on invasive species provides managers with the necessary information for successful restoration and conservation practices. Finally, paleolimnological research is being used to test hypotheses about biodiversity, extinction, and evolution, particularly with respect to microorganisms. Paleolimnology has made significant contributions to biogeography but also to our understanding of the significant impacts of humans on aquatic ecosystems. Perhaps most optimistically, this review shows that paleolimnological research offers a historical perspective that provides managers and policy makers with directions for successfully protecting, conserving, and restoring Earth systems.

Introduction

Pigments of photosynthetic organisms including chlorophylls (Chls), carotenoids, photoprotective compounds, and their derivatives are common in sediments of aquatic environments. They are produced by algae, phototrophic bacteria, and aquatic plants and may also be present in detritus from terrestrial or resuspended material and some invertebrate animals. Many groups of photosynthetic organisms are soft bodied and so leave few morphological remains in sediments. Therefore, biochemical fossils such as pigments may be the only signatures left behind. Pigments can be used to quantify past primary production in aquatic systems, and because many pigments show a degree of taxonomic specificity, they can provide information about past communities of algae or photosynthetic bacteria. Modern analytical techniques allow rapid and accurate separation, identification, and quantification of pigments in sediment stratigraphies, and through improved understanding of biogeochemistry and depositional processes, pigments are routinely used in the reconstruction of paleoenvironments with a wide range of applications (Figure 1).

Pigments as Biomarkers

Of the numerous pigments produced in the aquatic environment, those that are lipid soluble have superior preservation in the sedimentary record. Therefore, sedimentary Chls, carotenoids, and certain ultraviolet (UV)-absorbing lipids are more widely used than water-soluble compounds such as phycobilins. Chls, and carotenoids have several characteristics that make them suitable as Quaternary biomarkers:

1. They are widely distributed and are constituents of all photosynthetic organisms.
2. They are taxonomically specific, although the degree of specificity depends on the pigment. Most phototrophs produce a number of Chls and carotenoids. Some pigments such as Chl *a* are found in all algal groups, whereas others such as the carotenoid alloxanthin are found solely in cryptophytes, and oscillaxanthin is confined mostly to the cyanobacterial group *Oscillatoriaceae*. Affinities of pigments among taxonomic groupings of photosynthetic organisms are shown in Table 1.
3. They are relatively simple to isolate and quantify using a variety of analytical techniques dependent on the degree of detail and precision required.
4. They persist in the sediment environment, provided conditions are favorable (see later).

Structure and Nature of Pigments

Chlorophylls

Chls are magnesium coordination complexes of four pyrrole units (Figure 2(a); A–D) cyclically arranged with a fifth

isocyclic ring (Figure 2(a); E; reviewed in Jeffrey et al., 1997; Grimm, et al., 2006). There are four major Chl groups, of which three, including Chls *a*, *b*, and *c*, derive from algae; one group, the bacteriochlorophylls (Bchls), is produced by photosynthetic bacteria. Each is modeled on the same basic structure but distinguished by various modifications. In Chls *a* and *b* and Bchls *c*, *d*, and *e*, pyrrole D is reduced, and the structure of the ring is referred to as a chlorin; in Chl *c*, D remains unsaturated (called a porphyrin), whereas in Bchls *a* and *b*, both rings D and B are reduced (called a bacteriochlorin). Another feature that distinguishes the Chls is the presence of a long-chain alcohol appended to ring D (phytol present in Chls *a* and *b* and Bchls *a* and *b*; farnesol in Bchls *c*, *d*, and *e*; absent in Chls *c*). However, all Chls have a magnesium atom in the central ring.

Chls are susceptible to oxidative degradation leading to the formation of a number of colored breakdown products. For example, loss of the central magnesium atom from Chls leads to the formation of pheophytins. Loss of the phytol chain, usually from the action of chlorophyllase enzymes, leads to the formation of chlorophyllide. Further degradation causing loss of both the Mg and phytol chain leads to the formation of pheophorbides. Each of these breakdown products is readily detectable in sedimentary pigment extracts and can aid in the interpretation of stratigraphies. Bchls *c*, *d*, and *e* are especially susceptible to attack by substituent groups at ring B or C, leading to the formation of a number of homologues that can make the quantification of Bchl from pigment mixtures particularly challenging. Recently, a further group of compounds, steryl chlorin esters (SCEs), has been identified. SCEs are formed when sterols react with Chl molecules during passage through the gut of herbivores such as zooplankton. The nature of their formation has led to their use as an indicator of zooplankton grazing, but identification of these compounds usually involves the use of more complicated techniques such as mass spectrometry (MS; see later).

Carotenoids

Carotenoids are a larger group of compounds characterized by a long aliphatic polyene chain composed of eight isoprene (C_5H_8) units to give a long conjugated double-bond structure, the chromophore (Figure 2(b); reviewed in Britton et al., 1995; Jeffrey et al., 1997; Frank et al., 1999). Modifications to the end groups (Figure 2(b); A and B) of this basic structure allow different carotenoids to be formed. The two main divisions of carotenoids are the carotenes, which are composed solely of carbon and hydrogen atoms (e.g., β -carotene), and the more numerous xanthophylls, which carry one or more oxygen atom (e.g., fucoxanthin). Common end group modifications include the addition of a 5,6-epoxide to a cyclic end group as in fucoxanthin or the addition of a ketone group as in echinenone but can also include the addition of aldehyde, carboxy, carbomethoxy, methoxy acetate, and lactone groups.

Figure 1 Pigment mixtures extracted from a lake sediment core from Greenland composed mostly of carotenoids and pheophytins. Moving left to right, samples become increasingly dominated by orange carotenoids as the relative abundance of yellow pheophytins declines. Sample indicated with the arrow contains a high abundance of the red carotenoid okenone produced by purple sulfur bacteria. Photograph by S. McGowan.

Because of the extended double-bond system, carotenoids are susceptible to oxidation. Saturation of the double-bond system produces colorless compounds, and so, in contrast to the Chls, carotenoid derivatives are mostly undetectable by spectrophotometric techniques. However, early stages of carotenoid degradation may involve conversion to colored *cis*-isomers. Carotenoid chlorin esters, such as fucoxanthinol pheophorbide ester, may be formed when carotenoids and chlorins esterify on exposure to enzymes in herbivore digestive tracts, and so, they are of potential use as a grazing indicator.

UV-Absorbing Compounds

Compounds that absorb in the UV region (280–400 nm) have been isolated from aquatic organisms. These compounds are produced primarily by cyanobacteria in lake sediments and may function as photoprotectants because they are produced in response to UV exposure. One such pigment, scytonemin, is a yellow-brown, lipid-soluble dimeric pigment with a structure that is based on indolic and phenolic subunits (Figure 2(c); Squier et al., 2004). Scytonemin and its reduced counterparts have been used to infer past UV exposure in aquatic environments (Leavitt et al., 1997).

Light-Absorbing Properties

Pigments in phototrophs capture light either for photosynthesis or for protection from damaging levels of light. In both Chls and carotenoids, light absorption is caused by excitation of the electrons on the double-bond system in the chlorin/porphyrin ring and conjugated chain, respectively (called the chromophore). Absorbance of light at particular wavelengths of the visible spectrum causes Chls and carotenoids to have distinctive absorption spectra (and so colors) that are a useful aid in pigment identification (Figure 3; reviewed in Jeffrey et al., 1997; Britton et al., 1995).

Table 1 Photosynthetic pigments commonly found in the water column and sediments and relative stability in sedimentary environments rated from most stable (1)–(4) least stable (pigments rated 4 are rarely preserved in sediments) or unknown (–) stability

Pigment	Affinity	Stability
Chl <i>a</i>	All photosynthetic algae, higher plants	3
Chl <i>b</i>	Green algae, euglenophytes, higher plants	2
Chl <i>c</i>	Dinoflagellates, diatoms, chrysophytes	4
Bchls <i>a</i> and <i>b</i>	Purple sulfur and nonsulfur bacteria	–
Bchls <i>c</i> , <i>d</i> , and <i>e</i>	Green sulfur bacteria	–
Pheophytin <i>a</i>	Chl <i>a</i> derivative	1
Pheophytin <i>b</i>	Chl <i>b</i> derivative	2
Pheophorbide <i>a</i>	Grazing, senescent diatoms	3
Pyro-pheo (pigments)	Derivatives of <i>a</i> and <i>b</i> phorbins	2
Steryl chlorin esters	Chlorophyll derivatives from grazing	–
β-Carotene	Most algae and plants	1
α-Carotene	Cryptophytes, prochlorophytes, rhodophytes	2
Alloxanthin	Cryptophytes	1
Fucoxanthin	Diatoms, prymnesiophytes, chrysophytes, raphidophytes, several dinoflagellates	2
Diadinoxanthin	Diatoms, dinoflagellates, prymnesiophytes, chrysophytes, raphidophytes, euglenophytes, cryptophytes	3
Diatoxanthin	Diatoms, dinoflagellates, chrysophytes	2
Peridinin	Dinoflagellates	4
Canthaxanthin	Colonial cyanobacteria, herbivore tissues	1
Echinenone	Colonial cyanobacteria	1
Myxoxanthophyll	Colonial cyanobacteria	2
Oscillaxanthin	Cyanobacteria (<i>Oscillatoriaceae</i>)	2
Scytonemin	Colonial cyanobacteria	–
Zeaxanthin	Cyanobacteria	1
Lutein	Green algae, euglenophytes, higher plants	1
Neoxanthin	Green algae, euglenophytes, higher plants	4
Violaxanthin	Green algae, euglenophytes, higher plants	4
Isorenieratene	Green sulfur bacteria	1
Okenone	Purple sulfur bacteria	1
Rhodopinal	Purple sulfur bacteria	–
Astaxanthin	Herbivore tissue, N-limited green algae	4

Stability estimates from Leavitt and Hodgson (2001).

Chls absorb predominantly over blue and red wavelengths (Figure 3(a)) and are thus green in color, whereas carotenoids absorb blue and green light and so appear yellow, orange, or red (Figure 3(b)). Because light absorption properties are determined by the chlorin/porphyrin ring in Chls, loss of the phytol chain to form chlorophyllide has little impact on the spectrum, whereas loss of the magnesium atom changes the structure of the ring and causes a shift in the spectrum of pheophytin which is therefore yellow. In carotenoids, typical spectra have three absorbance maxima (Figure 3(b)); lutein and myxoxanthophyll), and because the chromophore rather than

Figure 2 Chemical structures of (a) Chl *a* consisting of cyclic tetrapyrroles with a fifth isocyclic ring (E) and phytol chain, (b) β -carotene showing typical carotenoid structure of a double-bond chromophore bound at each end by functional groups, and (c) scytonemin illustrating the dimeric structure based on indolic and phenolic subunits.

Figure 3 Absorption spectra of (a) Chl *a* and *b* and (b) carotenoids lutein showing the three absorption maxima typical of many carotenoid spectra: myxoxanthophyll showing how the presence of a sugar group in the structure has lengthened the chromophore and caused absorbance at longer wavelengths, and echinenone showing how the presence of the ketone end group has caused the loss of spectral fine structure.

the functional group determines light absorbance properties, carotenoids with very different end groups may have very similar absorbance spectra. This can impede the identification of certain carotenoids using absorbance characteristics alone. However, the addition of some end groups can affect light absorbance characteristics, for example, the addition of a ketone group can destroy the fine structure of the spectrum (Figure 2, echinenone) and the addition of a glycoside group can cause the chromophore to absorb at longer wavelengths (Figure 2, myxoxanthophyll). Therefore, although spectra cannot be used to conclusively identify pigments, they are a valuable aid to initial identification. Chls and carotenoids in solution obey Beer–Lambert law which states that absorbance is linearly proportional to their concentration. Thus, spectrophotometry is commonly used as a means of determining concentrations of pigments based on pigment-specific absorption coefficients.

Analysis

Pigment degradation can occur on exposure to light, oxygen, and heat, so care must be taken with pigment handling and storage. Sedimentary pigment samples should be frozen at $\leq -20^\circ\text{C}$ and freeze-dried in the dark shortly before analysis (Reuss and Conley, 2005). Analysis of the pigments within a sediment sample involves (i) extraction in suitable solvents, (ii) separation of the pigment mixture, (iii) identification of the pigments, and (iv) quantification. Today, this is typically achieved by using high-performance liquid chromatography (HPLC) and online photodiode array (PDA) spectrophotometry because they provide rapid and accurate analytical capabilities (reviewed in Leavitt and Hodgson, 2001).

(i) Extraction of pigments is achieved using a variety of organic solvents that are commonly acetone-based. A good

extraction solvent will be capable of dissolving pigments that range in polarity, and freeze-dried sediment is preferable to minimize interference from water in the sediments. Extraction usually involves soaking the sediments in solvent overnight at -4°C , followed by filtration and sequential washing until all pigments are removed.

- (ii) HPLC separates pigments primarily on the basis of polarity and mass. This is achieved by forcing solvents (the mobile phase) under pressure ($>2000\text{ kPa}$) through a separation column consisting of fine ($<10\text{ }\mu\text{m}$) densely packed particles (the stationary phase). Pigment separation is usually achieved by reversed-phase HPLC (RP-HPLC) where the stationary phase is nonpolar (i.e., lipid rather than water soluble) and the mobile phase is polar (water soluble). When the pigment mixture is carried through, polar pigments that have less affinity for the stationary phase are carried through the column more rapidly because of their greater affinity for the solvent (e.g., polar fucoxanthin elutes early in the chromatogram; see Figure 4). By slowly changing the solvent composition of the mobile phase so that it becomes less polar, more lipid-soluble pigments will be gradually released one by one, as their affinity for the mobile phase exceeds that of the stationary phase. Although polarity is a prime driver for elution order, mass of each molecule will further decide how long the molecule takes to be released from the column (the retention time). There are numerous conditions, solvent mixes, and methods suitable for the separation of pigments (see Leavitt and Hodgson, 2001), and choice of method is usually dependent on the separation efficiency, time taken, and pigments present.
- (iii) Identification of pigments is usually achieved using a combination of retention times and spectral characteristics. Once

eluted from the HPLC column, individual pigments are detected and retention times identified by scanning with a spectrophotometer at a fixed wavelength of maximal pigment absorbance (e.g., 450 nm) to produce a chromatogram (Figure 4). The position and retention time of the pigment on the chromatogram can be used to tentatively identify the pigment based on comparison with known commercial pigment standards under the same separation conditions. However, use of a PDA detector allows eluted pigments to be scanned simultaneously at multiple wavelengths to generate an absorbance spectrum, and this can be used to aid identification. For further identification of unknowns, the collection of the sample and its identification by MS (sometimes online) can be helpful in identifying problematic compounds such as Bchl homologues and degradation compounds.

- (iv) Quantification of pigments is achieved from spectroscopic properties using Beer–Lambert law. Internal calibration standards may be added to the extracts at the extraction or injection stage to correct for errors associated with analysis and handling. Calibration curves are constructed by injecting a known quantity of each pigment to allow conversion of chromatogram peak areas to concentrations. Such calibrations may be automated within the analytical software, but complex sedimentary mixtures usually require the expertise of an experienced operator to check that interpretations are correct. Final concentrations of pigments are normally expressed in nanomoles (nm) to correct for differences among pigment molecular weights and calculated relative to the organic matrix of sediment to reduce the effects of dilution by allochthonous mineralogenic material and because mineralization of labile bulk organics partly compensates for pigment degradation.

Figure 4 Typical RP-HPLC chromatogram of a pigment mixture. Pigments include (1) scytonemin, (2) Chl *c*, (3) fucoxanthin, (4) UV-absorbing compound *b* and (5) *a*, (6) internal standard Sudan II dye, (7) myxoxanthophyll, (8) alloxanthin, (9) diatoxanthin, (10) lutein–zeaxanthin, (11–13) carotenoid isomers, (14) canthaxanthin, (15) Chl *b*, (16) okenone, (17) Chl *a*, (18) echinenone, (19) pheophytin *b*, (20) pheophytin *a*, and (21) β -carotene. Note: Chromatograph has been loaded with excessive pigments for demonstration purposes. Reproduced from Leavitt PR and Hodgson DA (2001) Sedimentary pigments. Nonchromatographic analytical techniques for bulk unseparated pigments were used regularly prior to the development of HPLC (Swain, 1985). Chl derivatives can be measured on bulk extracts using a spectrophotometer while total carotenoids are measured on extracts that are first exposed to potassium hydroxide (saponification), which results in the removal of Chls. Because specific cyanobacterial carotenoids such as oscillaxanthin and myxoxanthophyll are relatively polar, they can be removed from pigment mixtures by phase separation and quantified using spectrophotometry that takes advantage of the carotenoids' distinctive spectra (Figure 3(b); myxoxanthophyll). Although the increased use of HPLC has meant that these techniques are now becoming obsolete, because they do not require specialist equipment, they can be useful in providing initial estimates of primary production.

An alternative nonchromatographic technique of estimating sedimentary Chl *a* concentrations is the use of reflectance spectroscopy (Das et al., 2005; cf. *Visible and Infrared Spectroscopical Applications*). This approach measures the size of troughs in reflectance spectra of sediments in either the visible near-infrared range ($600\text{--}760\text{ nm}$) or in the visible range (visible reflectance spectroscopy; VRS $650\text{--}700\text{ nm}$) to estimate changes in sedimentary Chl abundance (Michelutti et al., 2010). Accurate quantification of sedimentary Chl concentration can be achieved by calibration with samples measured by

HPLC, but overall, down-core pigment trends can be ascertained without the calibration stage. These techniques have been successfully used to record shifts in primary production in lakes from a wide range of trophic states (Michelutti et al., 2010). Therefore, because of its nondestructive nature, this novel analytical technique has great potential for the rapid screening of core sequences, where taxonomic detail about primary producers is not required.

Recently, there has been a growth in studies investigating the chemical structure of individual pigment isolates using MS techniques. MS analysis may be conducted directly on the HPLC eluent (online HPLC-MS), and techniques such as electron ionization, liquid secondary ion, and tandem MS are used to identify pigments by fragmenting molecules and identifying ionized fragments based on mass. Such techniques are usually employed as an identification tool in complex or unusual pigment mixtures that are difficult to identify based solely on spectral and retention characteristics. Another approach that is currently developing is the analysis of stable isotopes of carbon, nitrogen, and hydrogen (deuterium) in individual pigments using isotope-ratio MS (IRMS). This method requires a more lengthy extraction procedure to provide sufficient isolated pigment for IRMS analysis. Pigments are usually extracted using a combination of solid phase chromatography, reversed- and normal-phase HPLC, so this procedure can require a large amount of sediment to yield sufficient pigment for analysis. Pigment-specific isotope studies have the potential to tell us about changes in productivity and nutrient processing in individual algal taxa (Enders et al., 2008). Thus, interpretation is more straightforward than bulk sediments, where isotopic shifts can be caused by numerous factors. Stable carbon isotopes in pigments have also been used to investigate degradation processes in pheopigments by analyzing the isotopic composition of individual molecular fragments to determine the sources of phytol fragments added to molecules during degradation (Chikaraishi et al., 2007). Stable isotopes have been analyzed in Chl derivatives (porphyrins) from mid-Cretaceous shales and used to infer cyanobacterial nitrogen fixation. Therefore, taxonomic information may be inferred even in very heavily degraded samples that contain no intact diagnostic pigments (Kashiyama et al., 2008). The barriers to research in this area are the analytical time involved and the need for large samples, but as these problems are overcome, they have great potential in future paleoenvironmental research.

Preservation in Aquatic Environments

Some pigments degrade more readily than others (see Table 1; reviewed in Leavitt, 1993). Chls are relatively labile, but because they produce detectable breakdown products, they still leave identifiable remains in sedimentary records. Carotenoids, particularly carotenes, such as β -carotene are generally more stable, but some xanthophylls can be especially degradation prone; for example, fucoxanthin and peridinin are very labile because of the presence of a 5,6-epoxy-end group. Consequently, fucoxanthin is sometimes only present in the uppermost part of sediment records, whereas peridinin is rarely found in sediments. Although variability in degradation among pigments makes it difficult to reconstruct shifts in

relative algal abundance among groups, down-core patterns in individual pigments give good estimates of the abundance of specific algal groups. Thanks to past experimental work, there is now a thorough understanding of how degradation affects the interpretation of pigment stratigraphies. Therefore, changes in pigment preservation can give useful information about changes in past environmental conditions.

The general rules governing pigment degradation involve exposure to oxygen, light, and heat (reviewed in Leavitt, 1993; Cuddington and Leavitt, 1999). Because these conditions characterize the water column of many aquatic ecosystems, the majority of pigments (>95%) usually degrade before reaching the sediment. Degradation processes in the water column include chemically or microbially mediated oxidation, digestion during grazing by invertebrates, bacterial degradation, cell lysis, and enzymatic metabolism during senescence. These processes occur rapidly, with a half-life of days (Figure 5). Sedimentary pigment preservation is therefore largely dependent on how quickly pigments are degraded in the water column, which depends on lake morphometry and depth, sinking velocities of phototrophs, and grazing by zooplankton (which may negatively affect pigments by destruction from digestion but encourage preservation by increasing the sinking velocity of those pigments that become incorporated into heavier feces). Once deposited in the surficial sediments, pigment degradation is usually slower, although this will be dependent on conditions at the sediment–water interface. In oxygenated sediments where burrowing invertebrates are common, degradation via oxidation and digestion will continue. However, the conditions that characterize the sediments of many lakes tend to slow down pigment degradation such that it occurs over longer timescales (years). Evidence of such degradation in the upper sediments (~10 cm) is demonstrated by concentrations of labile pigments (e.g., fucoxanthin, Chl *a*) in sediment cores that commonly increase exponentially in the uppermost sediments. Once incorporated into the sediment below the zone of bioturbation, conditions are usually favorable for preservation, and most degradation involves slow saturation reactions that occur over timescales of millennia. Therefore, provided that pigments can pass the initial stages of deposition, they have been known to preserve intact for thousands of years and are therefore of considerable value to the paleoenvironmental record.

Pigments in Quaternary Deposits

Pigments have been used for paleoenvironmental reconstruction in a range of aquatic deposits. Because adequate preservation of pigments favors environments where pigments are rapidly buried and removed from light, heat, and oxygen, many lake sediments yield excellent pigment records. Records tend to be especially well preserved in lakes where bottom waters are anoxic or in shallow lakes where pigments are more rapidly incorporated into the sediment because sinking depths are small and production is dominated by algae growing on sediment surfaces. Most lake-based pigment reconstructions are recent (last few centuries) and some span the Holocene period, but pigments are increasingly being used for environmental reconstruction dating back to the Pleistocene

Figure 5 Pathways and rate of pigment degradation during transport through the water column and incorporation into the sediment. Adapted from Leavitt PR (1993) A review of factors that regulate carotenoid and chlorophyll deposition and fossil pigment abundance. *Journal of Paleolimnology* 9: 109–127; Cuddington K and Leavitt PR (1999) An individual-based model of pigment flux in lakes: Implications for organic biogeochemistry and paleoecology. *Canadian Journal of Fisheries and Aquatic Sciences* 56: 1964–1977.

and earlier (Tani et al., 2009; see later). In marine environments, lower rates of burial, deeper water columns, tidal exposure, and lower productivity may compromise preservation in some sites (Reuss et al., 2005). However, pigments have been used as effective indicators in coastal embayments and estuaries. For example, pigments were useful in reconstructing the eutrophication history of an anoxic estuary in Denmark over the past century (Ellegaard et al., 2006), and a >30-ka record extracted from Antarctica has yielded information about the development of marine flora during glacial–interglacial cycles (Hodgson et al., 2003). Geochemists are continuing to develop new ways of identifying and analyzing derivatives of Chl and carotenoid pigments to extract paleoenvironmental information from samples dating back millions of years (Kashiyama et al., 2008).

Sediment Pigments and Monitoring Records

Sedimentary pigments integrate algal production from the entire lake, including algae that live on the lake bottom (Buchaca and Catalan, 2008). They are therefore uniquely placed to quantify whole-ecosystem production which is usually not possible by plankton monitoring alone. However, comparison of sedimentary pigments with long-term phytoplankton monitoring records has revealed generally good correlations between the two in some sites. Comparisons of a 27-year algal monitoring record from Lough Neagh (Northern Ireland) showed strong correlations between the dominant cyanobacteria and measures of diagnostic pigments (Bunting et al., 2007). Similarly, a 20-year algal monitoring record compared with annually laminated (varved) sediments in an experimentally enriched Canadian boreal lake showed that pigments correlated well with algal standing crop and recorded the

striking increase in green algae and cyanobacteria that resulted from eutrophication (Leavitt and Findlay, 1994). Correlations with labile pigments from chrysophytes, diatoms, and dinoflagellates were weaker, but this was caused by the invariant nature of these algal groups as eutrophication progressed and the lability of some of these pigments.

In Himmerfjärden Bay (Swedish Baltic) when pigments from varved sediment cores were compared with >20 years of monitoring data, pigments from the predominant algal group (diatoms) correlated well with known records and registered past episodes of diatom blooms (Figure 6). Pigments from cyanobacteria and total algae did not match monitored records, possibly because picoplanktonic cyanobacteria were not enumerated in algal counts or because gas-vacuolated cyanobacteria did not sink into sediments as readily (Bianchi et al., 2002). This work also showed that sediment resuspension and differential settling of diatoms are important in this site because, although sediments were annually laminated, correlations among monitoring records and sediments were only evident on 5-year smoothed averages. Therefore, although pigments faithfully record changes in dominant algal groups in the water column, the fossil record may be biased due to preferential deposition of certain algal taxa, differential degradation of some pigments, and standard algal monitoring techniques that rarely sample the entire water column. Thus far, comparisons of pigments and contemporary records are disadvantaged by the short length of monitoring records that reduces the statistical power of correlation analyses and necessitate the analysis of the uppermost parts of the sediment record where degradation processes are most active. As long-term records continue to be gathered, better assessment of how phytoplankton pigments are integrated into the sediment record should become possible.

Figure 6 Comparison of indicator pigments extracted from annually laminated sediments in Himmerfjärden Bay (Baltic Sea) with monitored phytoplankton records for total phytoplankton biomass versus Chl *a*, total diatoms versus diatoxanthin and fucoxanthin, and total cyanobacteria versus zeaxanthin. Reproduced from Bianchi TS, Engelhaupt E, McKee BA, et al. (2002) Do sediments from coastal sites accurately reflect time trends in water column phytoplankton? A test from Himmerfjärden Bay (Baltic Sea proper). *Limnology and Oceanography* 47: 1537–1544, with permission. Copyright (2002) by the American Society of Limnology and Oceanography, Inc.

Eutrophication

Pigments have been used effectively in deeper lakes to record changes in water transparency associated with lake eutrophication (nutrient enrichment). In deep lakes where wind energy is insufficient to completely mix lake waters, bottom waters may become permanently anoxic (termed meromixis). If light penetrates into the anoxic layer, it can provide a habitat for photosynthetic sulfur bacteria that require both anoxia and light for photosynthesis. Specific purple and green sulfur

bacterial pigments (okenone and isorenieratene, respectively) declined in meromictic alpine Lake Tovel over the past 75 years, and this was interpreted to be caused by decreasing water transparency due to nutrient enrichment and increased algal growth in the upper water column (Lami et al., 1991).

One consequence of eutrophication in lakes and estuaries has been the widespread increase in cyanobacterial blooms. Because morphological fossils of cyanobacteria may not always preserve reliably in sediments, pigments are particularly useful in

assessing past blooms because these taxa have several indicator pigments. The cyanobacterial carotenoid myxoxanthophyll increased markedly after 1965, indicating increases in *Planktothrix agardhii* cyanobacteria in Lough Neagh as the lake became enriched (Bunting et al., 2007). In contrast, sedimentary pigments have also demonstrated that some lakes in the North American prairies and UK lowlands, as well as estuaries in the Baltic have sustained abundant cyanobacterial communities for millennia, suggesting that they are natural features of these systems (Bianchi et al., 2000; McGowan et al., 1999). Such information is valuable in determining appropriate restoration targets for ecosystems subjected to the effects of anthropogenic nutrient enrichment.

Aquatic Food Web Changes

Fossil pigments are important in demonstrating that changes in lake food web structure rather than nutrients can control algal communities in some circumstances. This work was pioneered in lakes in Michigan where three complete changes in fish communities (trout, cyprinid, bass) resulted in striking changes in body size of the zooplankton communities (Leavitt et al., 1989). Because zooplankton graze on algae in the water

column, when larger, more efficient zooplankton grazers were replaced with smaller species, most pigments increased in sediment cores, but there was a decline in deepwater blooms of chrysophytes. When larger zooplankton returned, deep-water chrysophyte blooms increased.

Sedimentary pigments are of particular value in monitoring algal community change in shallow lakes, where the majority of production may be associated with benthic algae that grow attached to surfaces and are difficult to monitor quantitatively. Over the past century, many shallow lakes in northern Europe have exhibited regime shifts and changed from a situation where there are few algae in the water column and there are abundant aquatic plants to one where the water is turbid with algal growth and the lake is devoid of aquatic plants. The effect of previous state changes on lake algal communities has been investigated using pigments and other proxies in sediment cores from a lake from Denmark. Analyses showed that remains of aquatic plants declined, while planktonic diatoms and cladoceran zooplankton that reside in the water column simultaneously increased, indicating that the lake changed to the turbid state ca. 1940 (McGowan et al., 2005; Figure 7). Pigments showed that when this happened, cyanophytes (myxoxanthophyll) in the water column increased, but

Figure 7 Changes in pigments from (a) diatoms (diatoxanthin), (b) cyanobacteria (myxoxanthophyll), and (c) total algae (β -carotene) compared with (d) other sediment remains of plant macrofossils, planktonic diatoms, and open-water cladocerans from sediments of shallow Lake Lading, Denmark. Adapted from McGowan S, Leavitt PR, Hall RI, et al. (2005) Controls of algal abundance and community composition during ecosystem state change. *Ecology* 86: 2200–2211.

diatoxanthin from benthic diatoms that grow attached to surfaces declined. This compensatory switch in the habitat of algal production resulted in little overall change in whole-lake algal abundance (indicated by β -carotene). Therefore, because sedimentary pigments integrate algal production from the entire lake basin, they can answer questions that would be difficult to approach by conventional monitoring techniques.

Atmospheric Deposition of Contaminants

Pigments have been used both in the detection of atmospheric contamination and in tracking lake response and recovery from its effects. Industrial contaminants containing sulfur and nitrogen have polluted lakes in many remote regions through deposition of 'acid rain.' Because acidification of Chl *a* (maximum absorbance 430 nm) leads to the formation of pheophytin *a* (maximum absorbance 410 nm), the 430 nmE: 410 nm absorbance ratio of bulk pigment extracts has been used to estimate lake water pH (Guilizzoni et al., 1992). Strong correlations between this ratio in surface sediments of alpine lakes and lake water pH and good down-core agreement with chrysophyte scale reconstructions corroborate its use, but because of degradative transformations from Chl *a* to pheophytin *a* in the uppermost sediments, such ratios must be interpreted cautiously.

Pigments also play an important role in detecting changes in water clarity associated with lake acidification. When lakes acidify, brown-colored dissolved organic carbon (DOC) concentrations decline and the water becomes more transparent. Experimental acidification recorded in sediments of a lake in western Ontario led to a sixfold increase in fucoxanthin from deepwater chrysophytes and elevated concentrations of UV-screening pigments when acidification was moderate, but at very low pH, UV penetration caused algal production to be suppressed (Leavitt et al., 1999). Similar lakes exposed to acidification from atmospheric pollution during the twentieth century also showed elevated levels of alloxanthin and fucoxanthin, indicating deepwater blooms of cryptophytes, chrysophytes, and dinoflagellates, and Chl *b* indicating proliferation of filamentous green algae (Vinebrooke et al., 2002; Figure 8). As well as acidifying lakes, nitrogen in industrial emissions has the potential to fertilize lakes that are less acid sensitive. In comparison to the effects of acid deposition, the effects of nitrogen deposition are only just becoming fully realized. Compound-specific stable isotope analysis of chloropigments from sediments in the Rocky Mountains of Colorado has provided an important piece of evidence that atmospheric deposition of nitrogen is fertilizing lakes in this remote area (Enders et al., 2008). The marked decline of the $\delta^{15}\text{N}$ signature of sedimentary Chl derivatives provides

Figure 8 Pigments in sediment cores of six lakes from Killarney Park, Ontario, Canada. Lakes vary in severity of acidification ranging from severe in (a) Acid Lake and (b) OSA Lake to moderate in (c) George Lake and (d) Bell Lake to negligible in reference lakes: (e) Teardrop and (f) Helen. The onset of industrial deposition over the lakes (ca. 1900) is indicated by dashed vertical lines. Reproduced from Vinebrooke RD, Dixit SS, Graham MD, et al. (2002) Whole-lake algal responses to a century of acidic industrial deposition on the Canadian Shield. *Canadian Journal of Fisheries and Aquatic Sciences* 59: 483–493, with permission from NRC Research Press.

convincing evidence that algal production was stimulated by an increase in nitrogen availability since 1950.

Hydrological Change

Pigments are excellent proxies in tracking past hydrological change in lakes because their production is strongly affected by water level changes. The hydrological regime of Lake Kinneret in Israel has been strongly managed over the past century for hydroelectric power schemes, wetland drainage, and conversion to a water storage reservoir. Paleopigments show that the increase in water level fluctuations has been associated with elevated algal production and degradation of water quality (Hambright et al., 2008).

Pigments have also been used to assess the response of delta lakes to changes in flood frequency in the Peace-Athabasca Delta (PAD; northern Alberta). Declines in the regularity of flooding cause ions and nutrients in PAD lake waters to become more concentrated because of lower inputs of dilute river waters. Lake levels also decline when flooding is infrequent, leading to the expansion of submerged and emergent aquatic vegetation which provides a habitat for algal growth. Pigments from lake sediments in the PAD demonstrate how these changes in lake conditions during periods of reduced flood frequency lead to increased lake primary production over decadal timescales (Figure 9; McGowan et al., 2011).

In closed-basin lakes, hydrological change may be accompanied by changes in salinity. In lakes of western Canada, pigments in surface sediments showed that there was a turnover of algal pigments along a salinity gradient (lutein-zeaxanthin and diatoxanthin replaced fucoxanthin as salinity increased), implying that changes in algal groups can infer past salinity changes (Vinebrooke et al., 1998). However, because salinity changes covary with water level, pigments in sediment-core stratigraphies of closed-basin lakes are likely to register a combination of the two factors. A further level of complexity arises in saline systems which become meromictic

(permanently stratified). Saline lakes in West Greenland stratify because dense saline water becomes overlain by less dense fresh water formed during winter ice cover (McGowan et al., 2008). These conditions favor anaerobic purple sulfur bacteria with characteristic pigments (e.g., okenone). Therefore, climate-driven changes in the water balance in closed-basin lakes in West Greenland lead to marked shifts in phototrophic community structure caused by a combination of changes in water level, lake mixing, and salinity.

Catchment Vegetation Changes

Changes in catchment vegetation can influence the flux of colored terrestrial DOC into lakes. Therefore, pigments can be indirect proxies for catchment vegetation by recording DOC-related fluctuations which influence light penetration into the water. DOC screens harmful UV radiation (UVR) from the water, and thus, lake sediments from Antarctic areas devoid of vegetation contain abundant UVR-screening scytonemin pigments produced to protect algae when DOC is absent. Similarly, lakes in montane environments where terrestrial sources of DOC are scarce are poorly buffered against the effects of droughts. In the Canadian Rockies, a period of drought resulted in an increase in abundance of UV-absorbing pigments in lake sediment cores because of a decline in DOC (Leavitt et al., 1997). Longer records spanning the Holocene indicate that UV-absorbing pigments are abundant in newly deglaciated lakes, reflecting the lack of terrestrial DOC in the catchment and the properties of lake waters turbid with suspended glacial flour that attenuate UVR less efficiently. Lakes situated at treeline may experience dramatic changes in DOC inputs; for example, Crowfoot Lake was above treeline >10000 BP, below treeline for the next 6000 years, and returned to treeline ~4000 BP (Leavitt et al., 2003; Figure 10). When below treeline, greater development of terrestrial vegetation (as indicated by pollen from N_2 -fixing plants)

Figure 9 Principal components analysis axis 1 scores from pigment assemblages of sediment cores from five PAD lakes. Shaded areas demarcate the periods of reduced flood frequency (b–e), and there was no change in water flux in ‘reference’ lake PAD05 (a). Axis 1 scores moving to the left of the diagram indicate an increase in pigment concentrations. Reproduced from McGowan S, Leavitt PR, Hall RI, et al. (2011) Interdecadal declines in flood frequency increase primary production in lakes of a northern river delta. *Global Change Biology* 17: 1212–1224.

Figure 10 Multiple proxies in sediments from Crowfoot Lake including UVR reconstruction using (a) the ratio of UV-absorbing pigment A: the sum of major carotenoids and (b) diatoms compared with (c) β -carotene as a measure of total production, (d) pollen from N_2 fixers, and (e) nutrients (total phosphorus) reconstructed from diatoms. Reproduced from Leavitt PR, Cumming BF, Smol JP, et al. (2003) Climatic control of ultraviolet radiation effects on lakes. *Limnology and Oceanography* 48: 2062–2069, with permission. Copyright (2003) by the American Society of Limnology and Oceanography, Inc.

increased inputs of DOC and augmented the attenuation of UVR, leading to a lower relative abundance of UV-screening pigments. This interpretation was corroborated by diatom-based UVR reconstructions. Further analysis of other algal pigments indicated that during periods of high UV penetration, algal production was 10–25-fold lower, and because lake nutrient concentrations did not change, UV was likely the causal factor in suppressing algal production. Pigments in surface sediments of sites spanning the treeline in Sweden appear to confirm that UV-screening compounds are more abundant in tundra than forested sites, highlighting the importance of DOC as a control on aquatic production and the sensitivity of pigments to ecotonal boundary changes (Reuss et al., 2009).

Long-Term Records

As cores are recovered from deeper lakes with records spanning thousands to millions of years, pigments have begun to be used in interpreting these continental-scale climate records through glacial and interglacial periods. Changes in rhodospinal, a pigment from anaerobic purple sulfur bacteria, were interpreted as being caused by alternating periods of lake anoxia and oxygenation in sediments of an Italian crater lake during the last glacial period (24–15 000 BP; Chondrogianni et al., 2004). Together with evidence from other proxies, including stable isotopes, sediment laminations, diatoms, and ostracods, it was suggested that the lake became well oxygenated during cooler drier periods because it was shallower and production declined (rhodospinal declines), whereas during warmer, wetter intervals, lake level and production (total carotenoids) increased, leading to lake anoxia (Figure 11).

One key issue that pigments can help to address is the comparison of climatic conditions in the previous (Eemian; Marine Isotope Stage 5e or MIS 5e) and present (Holocene) Interglacial periods. Pigments analyzed from lake sediment cores in Antarctica and Siberia (Lake Baikal) appear to confirm that the

Eemian was generally warmer than the Holocene (Fietz et al., 2007; Hodgson et al., 2006). In Lake Baikal, this was inferred from the higher concentrations of Chl *a* in Eemian sediments, which was interpreted as being caused by greater availability of phosphorus nutrient during the warmer Eemian (Fietz et al., 2007). The Lake Baikal pigment records also assisted in defining the start and termination of the MIS 5e Interglacial period (termed the Kazantsevo Interglacial) in this area of Russia. Probably the longest pigment sequences yet recovered were obtained from cores spanning the Plio–Pleistocene (4.5 Ma) period in Lake Baikal (Tani et al., 2009; Figure 12). Over these timescales, pigments are largely degraded, and so, the degradation products SCEs were analyzed to infer past phytoplankton composition. SCEs were categorized into indicators of diatoms, chlorophytes (SCEs deriving from Chl *b*), and dinoflagellates (SCEs formed with the dinoflagellate marker dinostanol). Using these markers, the pigments showed not only that there was generally good agreement with the marine benthic oxygen isotope record but also that there are periods of elevated dinoflagellate (4.5–4.2 and 1.7–1.3 Ma) and chlorophyte (2.5–2.6 Ma) abundance associated with periods of regional cooling and lower diatom abundance. This is the first time that phytoplankton other than diatoms have been used to infer past change in these long records.

Conclusions

Recent decades have seen a great expansion in analytical capabilities and improved understanding of how pigments and their degradation products are incorporated into the sediment record. Pigment analysis has become a routine part of multi-proxy studies and contributes information that would be impossible to derive from other proxies. As these techniques continue to be used in an increasing range of environments, it is predicted that pigment analysis should make a valuable contribution to the Quaternary sciences in the future.

Figure 11 A combination of proxies including lithology, magnetic susceptibility, bioturbation index, the concentration of purple sulfur bacterial pigment rhodopinal, hydrocarbon, and oxygen content of the organic matrix (oxygen and hydrogen index), total carotenoids, and $\delta^{18}\text{O}$ stable isotopes from diatom silica were used to infer historic changes in water level in Lake Albano. Multiproxy Approaches

Introduction

Paleolimnology is a multidisciplinary science, and thus it naturally lends itself to multiproxy studies. Nonetheless, most of the early paleolimnological research had a single-proxy focus, and, although single-proxy studies can be very informative and provide defensible conclusions, multiproxy approaches are becoming increasingly popular because they allow for more complete and robust environmental reconstructions. A search in the *Journal of Paleolimnology* using the keyword 'multiproxy' (with no filters) shows a steadily rising number of manuscripts that report on multiproxy data over the past 12 years (Figure 1). Multiproxy studies in the current paleolimnological arena are commonplace, and data spanning a wide breadth of topics from aquatic chemistry, catchment vegetation, and atmospheric deposition can often be found in a single manuscript.

Birks and Birks (2006) identify eight basic requirements for a multiproxy study, including (1) the need for clear research questions at the outset, (2) a strong leader, (3) carefully selected study sites and coring locations, (4) proper data storage and coordination, (5) a reliable sediment chronology, (6) clear presentation of the results, (7) the proper use of numerical techniques, and (8) interpretation and publication of large amounts of data. These are useful guidelines for any paleolimnological study but are especially critical requirements for a successful multiproxy investigation, as problems can become exacerbated when dealing with many collaborators and large amounts of data. There is no doubt that multiproxy studies require individuals who are detail oriented in the initial planning stages but keep the broad perspective of the study goals in mind, especially when writing manuscripts. Despite these apparent difficulties, the benefits of a multiproxy approach typically far outweigh the challenges involved.

Over the last several decades, there have been tremendous advancements in paleolimnology in both the development and interpretation of new proxies as well as in numerical techniques for analyzing complex stratigraphic data (Cohen, 2003; Smol, 2008). The number of analyses that can be performed on lake sediments to address a wide range of pressing environmental concerns is continually increasing. In fact, a limiting step in many multiproxy studies is the finite amount of sediment that is available for analyses. Reviews detailing the vast array of sedimentary proxies are given in Cohen (2003), Last and Smol (2001a,b), Smol (2008), and Smol et al. (2001a,b). In a properly designed study, the inclusion of several proxies provides for a greater understanding and often additional insights into different aspects of limnological processes.

Multiple Proxies to Obtain a Holistic Approach to Paleolimnological Reconstructions

The most common reason to adopt a multiproxy approach in a paleolimnological study is simply to gain a broader perspective

on environmental change than can be offered by using a single proxy. For example, a multiproxy study can provide a more complete history of change that includes independent data on the limnological regime, catchment, and atmospheric deposition. Often such robust paleoenvironmental reconstructions are required to refute possible competing hypotheses believed responsible for change, and it is only then that legislators and governments will take action to curb environmental threats. Perhaps one of the best examples of how a multiproxy paleolimnological approach was applied to tackle a common environmental issue is the example of acidification of lakes and rivers (see also Lake Chemistry).

Acid rain, or more appropriately, acidic deposition, occurs when emissions of sulfur and nitrogen oxides are converted into sulfuric and nitric acids in the atmosphere and return to the land in either dry or wet deposition. Although there are natural sources of acidic precipitation, the largest sources in many regions are anthropogenic, including the burning of coal and other fossil fuels and the smelting of sulfur-rich ores. The acidification of lakes and waterways was first recognized as a potential environmental problem in the 1950s, although acidic deposition had been occurring on a large scale since the onset of the Industrial Revolution, over a century earlier. The effects of acidic deposition on lakes and rivers are complex but typically involve a marked decrease in lake water pH in poorly buffered systems. The acidification of catchment soils can also impact aquatic chemistry. For example, inorganic monomeric aluminum (Al^{3+}), which, at certain concentrations, is toxic to fish and other biota, is mobilized from acidifying catchment soils and eventually leaches into lakes and waterways. Other impacts on aquatic chemistry include declines in the concentration of dissolved organic carbon (DOC), which acts as a natural sunscreen protecting aquatic biota from harmful ultraviolet rays. These changes in water chemistry have dramatic impacts on the size and composition of algal and invertebrate communities, as well as noticeable signs of stress on fish populations, including decreased fecundity and in some instances complete extirpation. Many of these effects have been well documented during an experimental acidification of a boreal softwater lake (Lake 223) in the Experimental Lakes Area of northwestern Ontario, Canada (Schindler et al., 1985).

Acid rain was a highly politicized issue, especially during the peak of its public concern in the 1980s. Governments were initially reticent in their actions to pass legislation that curbed acid-causing emissions until it was unequivocally demonstrated that such emissions were indeed responsible for acidifying lakes and rivers. Opponents of taking legislative action claimed (often with no real evidence) that the acid lakes were either always acidic or that the acidification was part of a natural long-term soil acidification process that had been occurring since lake formation. Others argued that it was changes in catchment vegetation that led to the acidification, not the emissions. With little to no long-term monitoring data,

Figure 1 Search results, with no filters, showing the number of manuscripts that contain the term 'multiproxy' over the past 12 years in the *Journal of Paleolimnology*.

a multiproxy paleolimnological approach was the only way to answer critical questions such as: Have the lakes acidified? If so, by how much? And what are the causes of acidification?

Large-scale paleolimnological acidification programs were undertaken in the United States (Charles and Smol, 1990; Charles and Whitehead, 1986; Whitehead et al., 1990), Canada (Dixit et al., 1995), and the United Kingdom and Scandinavia (Battarbee et al., 1990). The first step was to identify and develop proxies that could be used to infer lake water acidity. This was accomplished through surface sediment training sets, or calibrations sets, mainly involving diatoms and, to a lesser extent, chrysophytes. Modern-day assemblages of diatoms and chrysophytes were shown to have distributions that were strongly controlled by lake water pH (Battarbee et al., 2010). This allowed for the computation of diatom and chrysophyte-based pH transfer functions that could be applied to fossil assemblages preserved in sediment cores to quantitatively infer past lake water pH.

An oft-cited example of diatom- and chrysophyte-inferred pH change is from Baby Lake, located near Sudbury, Ontario, Canada (Dixit et al., 1992). For several decades, the Sudbury region was one of the largest point sources of sulfur emissions in the world, due to the massive mining and smelting activities that occurred in the area. The large output of sulfur emissions, coupled with the poor buffering capacity of the underlying geology, made Sudbury area lakes ideal study sites to investigate the impacts of acidic deposition. More importantly, local governments and scientists had the foresight to undertake water monitoring programs, given the potential for damage from the sulfur emissions. Baby Lake was one such site where pH measurements were available, beginning in 1968. The historical pH measurements provided ground-truthing data for the diatom and chrysophyte transfer functions. The diatom and chrysophyte pH inferences showed that, prior to mining activities, Baby Lake had a circumneutral pH, near pH 6.5. The inferred pH showed a dramatic decline beginning around 1940, reaching a low of pH 4.2 by the mid-1970s, coincident with the period of intensive smelting activities and massive sulfur emissions. With the closure of a nearby smelter, the lake water pH started to show signs of recovery back to pre-industrial pH levels. Importantly, the trends in the measured

Figure 2 Diatom (solid circles) and chrysophyte (open circles) inferred pH reconstructions from Baby Lake, near Sudbury, Ontario. Also shown are the measured pH data (squares) dating back to 1968. Reproduced from Hutchinson TC and Havas M (1986) Recovery of previously acidified lakes near Coniston, Ontario, Canada, following reductions in atmospheric sulphur and metal emissions. *Water, Air and Soil Pollution* 29: 319–333; Dixit SS, Dixit AS, and Smol JP (1992) Assessment of changes in lakewater chemistry in the Sudbury area lakes since preindustrial times. *Canadian Journal of Fisheries and Aquatic Sciences* 49: 8–16, with permission.

pH data closely matched those of the paleolimnological data (Figure 2). Similar profiles of marked pH declines, coincident with the onset of large-scale industrial activities, were reconstructed for many other Sudbury area lakes and indeed in many acid-sensitive regions around the world (Smol, 2008).

The timing of species changes and lake water pH inferences have also been used in conjunction with geochemical analyses to confirm the source of pollution. The paleolimnological acidification program in the United States focused on acid-sensitive regions that received large amounts of acidic

deposition, such as the Adirondack Mountains in New York State. One of the study sites in the Adirondack Mountains was Deep Lake, a headwater lake that was known to be acidic (pH ~ 4.8) and fishless in the 1980s. Lake water pH reconstructions showed that Deep Lake was initially acidic in preindustrial times, but became increasingly acidic during the 1900s, coincident with increases in acidic emissions to this region (Charles et al., 1990). Sedimentary analyses of coal and oil soot particles, polycyclic aromatic hydrocarbons (PAHs), and metals such as lead and vanadium showed clear increases coincident with the onset of large-scale fossil fuel combustion and also with the timing of aquatic species changes and the beginning of inferred pH declines (Figure 3). The multiproxy approach of using both species and geochemical data further implicated acidic emissions as the cause of widespread lake acidification.

There was mounting evidence demonstrating the linkages between industrial emissions and acidifying waterways, but there were still claims that long-term changes in catchment soils were wholly or partly responsible for lake acidification. An example from Scandinavia involves the argument that acidification had occurred as a result of a decline in traditional forms of agriculture, which led to afforestation and hence an increase in the humus content of soil, which in turn resulted in the acidification of lakes due to shifts in ion exchange processes in watershed soils (Rosenqvist, 1977, 1978). To test this hypothesis, Anderson and Korsman (1990) analyzed pollen grains preserved in lake sediments in order to investigate the role that vegetation shifts and land-use changes may have had on lake water pH. They used an historical analog approach where they argued that a well-documented decline of farming activities in the Hälsingland region of Northern Sweden during $\sim$ AD 500 (the so-called migration period) should result in similar afforestation and subsequent pH declines in lakes. Their pollen analyses showed that, similar to present-day, afforestation did occur $\sim$ AD 500; however, the diatom data did not show any signs of acidification. This was in sharp contrast to modern times, where one study lake showed a recent acidification, as predicted with acidic deposition.

The combination of aquatic, terrestrial, and geochemical proxies used in the acid rain programs resulted in holistic

paleolimnological reconstructions and provided clear evidence that acidic emissions were largely responsible for lake acidification. Alternative hypotheses suggested by the opponents of legislative action were strongly and consistently refuted in many studies. The strength of this multiproxy approach ultimately resulted in legislation that led to marked reductions in acid-forming emissions.

Multiple Proxies to Identify Stressors and Effects

Many environmental or ecological studies can identify either stressors or effects, but rarely both. A multiproxy paleolimnological approach has the advantage of being able to identify environmental stressors and the associated effects, as was clearly shown in the aforementioned acid rain programs of the 1980s and 1990s. In the preceding section, it was discussed how multiple proxies identified acidic emissions as the key stressor involved in widespread lake acidification. However, one of the most disconcerting effects of lake acidification, at least to the public at large, was the disappearance of fish species. The effects of acidification on fish reproduction and survival were well documented during the artificial acidification of a softwater boreal lake (Lake 223) in the Experimental Lakes Area of northwestern Ontario, Canada (Schindler et al., 1985). However, in lakes with little or no monitoring data, it proved difficult to link the decline in fish populations with acidification. It is possible that fish were never present in some naturally acidic lakes. If fish populations could be reconstructed from lake sediments, it would be possible to link their demise with the onset of acidification, or even to determine if a lake was naturally fishless.

Historical fish populations are difficult to reconstruct from lake sediments because fish leave few fossil remains in the sedimentary record. Often, more indirect techniques are required. One common approach is the use of subfossil remains (mandibles) of *Chaoborus* larvae (Figure 4), which live in the limnetic zone of lakes, feeding on zooplankton, and can tolerate a wide range of pH levels. *Chaoborus* larvae differ in their patterns of vertical migrations, as well as size and color, all of

Figure 3 Measured concentrations of lead (Pb), polycyclic aromatic hydrocarbons (PAHs), coal soot, oil soot, and vanadium (V) measured in the Deep Lake sediment core from the Adirondack Mountains (New York, USA). Reproduced from Charles DF, Binford MW, Fry BD, et al. (1990) Paleocological investigation of recent lake acidification in the Adirondack Mountains, N.Y. *Journal of Paleolimnology* 3: 195–241, with permission.

which can affect their susceptibility to fish predation. Thus, the presence or absence of planktivorous fish is one of the main factors that can affect the distribution of *Chaoborus*. Certain taxa (e.g., *Chaoborus punctipennis*, *Chaoborus albatus*, *Chaoborus trivittatus*, and *Chaoborus flavicans*) exhibit diurnal migration and only enter the upper water column to feed at night when fish, which are visual predators, have limited vision. The only known taxon in the Northeastern United States and Canada that does not exhibit diurnal vertical migration is *Chaoborus americanus*, and thus, it rarely occurs in lakes with planktivorous fish. *C. americanus* has colonized lakes from which fish have been extirpated, and it has been extirpated itself in lakes from which fish have been reintroduced (Evans, 1989; Nilssen, 1984).

In the Adirondack region of New York State, USA, Uutala (1990) examined *Chaoborus* remains to assess the status of fish populations in five lakes over the past several centuries. One of the study sites, Windfall Pond, was a lake that had not acidified and currently had viable fish populations. The sediment core from this site contained the remains of only *Chaoborus* taxa that practiced vertical migration, indicating the long-term presence of fish in this lake. Other study sites including Brooktrout Lake, Deep Lake, and Upper Wallace Pond had all acidified in recent years and were all currently fishless. The appearance of the nonmigratory *C. americanus* in the recent sediments of Brooktrout Lake (~1970s) and Deep Lake (~1940s) indicates that these two lakes lost their fish populations in recent decades. Upper Wallace Pond showed a dominance of *C. americanus* throughout its entire core, indicating this lake likely never supported planktivorous fish.

The combination of *Chaoborus* analysis with diatom-inferred pH reconstructions and/or analyses of metal chemistry from the Adirondack lake sediment cores clearly identified

both stressor (acidification) and effects (fish extirpations). This type of multiproxy approach has direct management implications as it identifies which lakes should qualify for fish restocking programs.

Multiple Proxies to Resolve Competing Hypotheses of Environmental Change

Aquatic ecosystems change through time in response to natural and anthropogenic stressors. Multiple proxies are often required in order to bring resolution to competing hypotheses of change. Several proxies can be used in support of one another (i.e., the weight of evidence approach), thereby strengthening paleoenvironmental interpretations, or can be used in what Birks and Birks (2006) refer to as 'data splitting' where one proxy is used to interpret stratigraphic changes in another independent proxy.

An example of 'data splitting' and the use of supporting proxies is provided by Wolfe et al. (2001) who recorded marked and near-synchronous change in fossil diatom assemblages in two alpine lakes in the Colorado Front Range (USA). The diatom assemblage prior to the ~1900s was characteristic of oligotrophic alpine lakes and was composed primarily of *Aulacoseira* taxa, small benthic *Fragilaria sensu lato* taxa, and various *Achnanthes* taxa (Figure 5). After ~1900, the planktonic taxa *Asterionella formosa* and *Fragilaria crotonensis* increased in abundance, and post ~1950, *A. formosa* became the dominant taxon in both study sites. Prior research conducted in Arctic regions showed marked shifts in diatom assemblages (reviewed in Smol and Douglas, 2007) that were attributed to lengthened growing seasons associated with recent climate warming. The increased percentage of planktonic taxa recorded in the alpine lakes could plausibly be explained by climate warming. This is especially true given the remote location of the alpine lakes and the fact that high-altitude ecosystems, similar to high-latitude ecosystems, are among the most susceptible to climate change. However, Wolfe et al. had reason to believe that the recorded diatom changes in their specific study lakes were also driven by nutrient additions, specifically atmospheric deposition of fixed nitrogen from anthropogenic sources. The reasons for this suspicion included the fact that *A. formosa* and *F. crotonensis* are well-known indicators of nutrient enrichment, and their increase suggests a response to nutrients rather than climate. In addition, the study sites were located along an air mass trajectory that carries atmospheric pollution from the highly populated Denver-Fort Collins urban corridor (~2.4 million people at the time of the study) in an easterly manner up the Colorado Front Range.

To test their hypothesis, Wolfe et al. analyzed stable isotopes of nitrogen ($\delta^{15}\text{N}$) in the sediments. In both study lakes, they recorded a trend toward lighter isotopic values post ~1950 coincident with the shift from oligotrophic to mesotrophic diatom taxa (Figure 5). The decline in sedimentary $\delta^{15}\text{N}$ values was suggested to reflect increasing additions of isotopically depleted N compounds from areas east of the Colorado Front Range. The isotopic depletions are consistent with fertilizer produced from the Haber-Bosch process, which results in NH_3 that has $\delta^{15}\text{N}$ values of $\sim 0 \pm 3\%$. In addition,

Figure 5 Fossil diatom stratigraphies and profiles of sedimentary $\delta^{15}\text{N}$, Pb, and ^{210}Pb dating profiles for Sky Pond (a) and Lake Louise (b), two lakes in the Colorado Front Range that have been affected by anthropogenic atmospheric N-deposition. Reproduced from Wolfe AP, Baron JS, and Cornett RJ (2001) Anthropogenic nitrogen deposition induces rapid ecological change in alpine lakes of the Colorado Front Range (USA). *Journal of Paleolimnology* 25: 1–7, with permission.

confined animal feeding operations, which rose from 1.4 to 3.7 million head between 1940 and 1970, have NH_3 emission that range from -15 to -9% . These isotopically depleted N sources are consistent with the $\delta^{15}\text{N}$ declines recorded in the study cores.

Although sediment diagenetic effects can alter $\delta^{15}\text{N}$ values, previous research has suggested that the $\delta^{15}\text{N}$ in sediments is typically representative of the isotopic content in the water column (Brenner et al., 1999). Moreover, the timing of the isotopic depletion is consistent with the rise in population, which tripled between 1950 and 1995, and the associated increase in industrial and agricultural activities. Still, it was previously suggested that the study sites, at elevation >3300 m above sea level, were above the limit for deposition of anthropogenic emissions by upslope air masses. To further dispel this notion, Wolfe et al. analyzed the sediment for stable lead (Pb) concentrations. The lead profile shows an increase in concentration in pre-1930s sediments consistent with mining and smelting activities in the area (Figure 5). Further increases occur after this time associated with the addition of alkyl Pb additives to gasoline in the early 1920s. Both profiles also record a synchronous decline in lead concentrations that mark the placement of strict controls on leaded gasoline beginning in the 1970s. The lead data, together with $\delta^{15}\text{N}$ isotopic data, clearly demonstrate that anthropogenic emissions are capable of reaching the elevation of the study sites. The Wolfe et al. study illustrates some of the advantages of ‘data splitting’ as well as using proxies in support of one another to identify the key environmental stressor causing ecological change.

Multiple Proxies to Detect Differential Limnological Responses in Spatially Separated Lake Habitats

Lakes are complex ecosystems, and a single proxy does not always reveal sufficient information to demonstrate how a lake responds to an environmental stressor. For example, in some instances, a decoupling in limnological processes can occur between spatially separated habitats. By selecting proxies that characterize different lake strata, it is possible to track changes in distinct lake zones. For example, planktonic diatoms will reflect epilimnetic conditions, and profundal chironomids will record changes in the hypolimnion.

Little et al. (2000) used a multiproxy approach involving (1) diatoms to reconstruct epilimnetic nutrient concentrations and (2) chironomids to infer hypolimnetic anoxia in Gravenhurst Bay (Ontario, Canada), a water body that has well-documented eutrophication and recovery events. A typical lake response to eutrophication is that the added nutrients increase epilimnetic primary production, resulting in increased organic matter settling to the hypolimnetic water, which in turn becomes anoxic due to decomposition of the excess organic material. Little et al. used a diatom-based total phosphorus (TP) inference model to track the onset of eutrophication at Gravenhurst Bay, which began with the arrival of European settlers in the mid-1800s. As expected, hypolimnetic oxygen levels, inferred from chironomid assemblages, indicated that anoxic conditions became more prevalent with the onset of this eutrophication. The highest diatom-inferred TP (DI-TP) values occurred around 1950, which also corresponded with the period of the most severe

hypolimnetic oxygen deficits, as marked by the disappearance of profundal chironomid taxa. Following 1972, sewage inputs to the bay declined and the diatom assemblages tracked this recovery, showing decreases in inferred TP and a shift back to oligotrophic taxa. Interestingly, the benthic chironomids showed no parallel recovery. The proxy data are entirely consistent with monitoring data that show continued declines in surface water TP concentrations and persistent anoxia in the deepwater. The reason for this decoupling remains unclear, but the study serves as an example of the importance of using different proxies in order to track changes in spatially separated lake habitats.

MacDonald et al. (2009) provide another example of a decoupling between chironomids and indicators of lake production in a multiproxy investigation in a small lake in the Northwest Territories of Canada. In this study, MacDonald et al. used organic matter content by loss-on-ignition (LOI) and biogenic silica (BSi) as indicators of aquatic production in conjunction with chironomid-inferred July air temperature and summer water temperatures to reconstruct climatic conditions over the past ~ 2000 years. Their records of LOI, BSi, and chironomid assemblages are generally in good agreement, showing shifts in lake production that are consistent with warmer and more productive conditions prior to the Little Ice Age (LIA), as well as declines in lake production and inferred temperatures during the LIA. The increased warming of the twentieth century is marked by LOI and BSi concentrations that equal or exceed that of any other time during the past 2000 years. However, the chironomid-inferred temperatures show no evidence of any recent warming trend. It is hypothesized that enhanced lake water stratification during twentieth century warming has led to decreased oxygen and lower temperatures of the hypolimnion of the lake, resulting in an ambiguous chironomid response with respect to warming. This study demonstrates the value of a multiproxy approach to better understand how different lake zones may respond to recent climate change.

Multiple Proxies to Track Multiple Environmental Stressors

Lakes are being impacted by multiple stressors with the pervasive effects of climate warming superimposed on more regional stressors, including catchment development, eutrophication, acidification, and deposition of atmospheric contaminants, as well as newly identified threats such as calcium depletion (Jeziorski et al., 2008). All of these stressors lead to widespread concern over the general health of lakes and can frustrate lake managers and government agencies with respect to identifying the most important stressors affecting lakes. Multiproxy studies can pinpoint the principle stressor affecting a given set of lakes, which greatly assists regulating agencies in effectively spending their often limited budgets for lake remediation projects. Below, we discuss two examples of using multiple proxies to assess the role of multiple stressors on ecological change. The first example concerns the issue of increasing algal blooms in Lake of the Woods (LoW), Ontario, Canada, and the second involves assessing the role of animals as biological vectors of nutrients and contaminants into freshwaters.

Assessing the Factors Leading to Increased Algal Blooms in Lake of the Woods (Ontario, Canada)

Cyanobacterial blooms are increasingly reported as a water quality concern in lakes globally. These blooms obviously degrade the recreational enjoyment of the lakes but also have serious ecological ramifications as they increase turbidity and kill off macrophytes that provide important habitats for fish and invertebrates. When the blooms die off, they can create anoxic conditions that can lead to fish kills. Moreover, cyanobacteria constitute a public health threat as some taxa produce toxins that can lead to serious and sometimes fatal diseases (Pearl and Huisman, 2008). Nutrient enrichment of water by intensive shoreline development, as well as industrial and agricultural activities, often drives the growth of these algal blooms, but other factors such as climate warming and increased thermal stratification can also be important.

Lake of the Woods (LoW) is an international water body spanning the Canadian provinces of Ontario and Manitoba and the state of Minnesota in the United States. The lake is large (3850 km²) and contains numerous basins with nearly 14 000 islands and hundreds of inlets and bays. It has a long history of human disturbance dating back to the 1850s, including land clearance by European settlers, logging and sawmill activities, and at the turn of the twentieth century, the construction of dams for water level regulation and hydroelectric power. The lake is popular for recreational activities, and there is extensive cottage development around its shoreline. In recent years, lake residents have reported an increase in the frequency and intensity of late-summer cyanobacterial blooms in the northern portion of the lake (DeSellas et al., 2009). However, there are little long-term monitoring data to assess whether these blooms represent an actual deviation from natural variability.

Rühland et al. (2010) conducted a paleolimnological study to investigate the role that multiple stressors, including nutrient enrichment, dam construction, and recent warming, may have had on exacerbating nuisance algal blooms in LoW. To do so, they recovered sediment cores from three separate basins that varied in trophic status, due to differences in the degree of their connectivity to the Rainy River, which accounts for over 70% of the inflow to LoW and is the main source of nutrient inputs into the lake. Two of the coring sites, PP1 and Bigstone Bay, are meso-to-eutrophic basins and are sites where recent algal blooms have been recorded. The other coring site, Whitefish Bay, is hydrologically isolated from the nutrient-rich flow from the Rainy River and is currently oligotrophic; no recent algal blooms have been documented there. DI-TP models were used to estimate the timing, magnitude, and direction of water quality change in these three basins. In addition, sedimentary chlorophyll *a* concentrations were inferred, using spectral reflectance (Michelutti et al., 2010), to provide an indication of whole-lake production.

Diatom assemblages at all sites showed marked changes in response to hydro-management activities and recent climate warming, indicating an ecological response to multiple stressors. However, at the nutrient-rich sites (PP1 and Bigstone Bay) where nuisance blooms occur, DI-TP showed either little-to-no change over time or even decreases over the last few decades, which is entirely consistent with remediation efforts since the mid-1970s, resulting in a steady decline in TP loading

from the Rainy River. This indicates that increased TP concentration is not the main trigger of recent nuisance algal blooms in LoW. The chlorophyll *a* reconstructions show increases over the past several decades in the two nutrient-rich sites (PP1 and Bigstone Bay), but no change in the oligotrophic Whitefish Bay (Figure 6), and therefore are likely tracking increased intensity of cyanobacterial blooms. The chlorophyll *a* reconstructions provide strong evidence to support the lake residents' observations that nuisance algal blooms have been increasing in recent years in the northern portion of the lake. Significant ($p \leq 0.05$) correlations between temperature and chlorophyll *a* reconstructions indicate that temperature likely plays a key role in the recent algal blooms. The possible mechanisms by which temperature is driving an increase in algal blooms include increased duration and strength of thermal stratification, which favors the buoyant cyanophytes (e.g., Pearl and Huisman, 2008), longer ice-free seasons affecting nutrient availability (e.g., seasonal N-limitation), and warmer temperatures that may influence internal TP loading.

The multiple proxies used in the Rühland et al. study answered several important lake management questions pertaining to cyanobacterial blooms in LoW. First, the data indicated that lake water TP may not be the ideal indicator of aquatic ecosystem health. Second, the chlorophyll *a* reconstructions confirmed the lake residents' perception that nuisance algal blooms were indeed increasing in recent years. Third, the diatom data (along with supporting water quality monitoring data) demonstrated that the recent algal blooms were not driven by increases in lake water TP alone, and the

Figure 6 Inferred sedimentary chlorophyll *a* profiles in the nutrient-rich sites PP1 and Bigstone Bay, as well as for the oligotrophic basin, Whitefish Bay in Lake of the Woods. An increase in recent algal blooms has been documented in PP1 and Bigstone Bay, but not in Whitefish Bay. Reproduced from Michelutti N, Blais JM, Cumming BF, et al. (2010) Do spectrally inferred determinations of chlorophyll *a* reflect trends in lake trophic status? *Journal of Paleolimnology* 43: 205–217, with permission.

triggers for nuisance blooms are complex, with climate change being an important contributor to the increased blooms.

Animals as Biological Vectors of Nutrients and Contaminants

Animals that cross ecosystem boundaries can transport nutrients and other substances from one food web to another, often with beneficial consequences for the recipient ecosystem. In many instances, this transport occurs from marine to terrestrial environments. For example, sea turtles that spend most of their life feeding in the ocean subsidize nutrient-poor dune ecosystems, when they come ashore to nest, via marine-derived nutrients from waste products that enhance vegetation and promote dune stabilization (Hannan et al., 2007). Other examples of 'biovectors' that transport and focus nutrients from the ocean to inland sites include sea lions, whales, salmon, and seabirds (Blais et al., 2007; Fariña et al., 2003; Michelutti et al., 2009). When the waste products from these biovectors are deposited in or around lakes, paleolimnology can be used to track the associated limnological effects as well as changes in population dynamics of the biovectors themselves.

The decline of fish populations in many coastal regions around the world has been attributed to many factors including overfishing, pollution, habitat destruction, and climate change. The lack of long-term monitoring data for most fish stocks makes it impossible to identify the potential stressors responsible for the declines. Sockeye salmon (*Oncorhynchus nerka*) represent a commercially and culturally important salmon species on the west coast of North America. Sockeye salmon hatch in nursery lakes, where they spend the first 1–3 years of their lives before heading out to the ocean where they spend the next 2–3 years and accumulate >95% of their biomass (Naiman et al., 2002). In the ocean, the salmon feed on plankton, squid, and small fish, and due to their high trophic position, they preferentially accumulate greater levels of the heavy ^{15}N isotope, relative to the light ^{14}N isotope. The adult salmon return upstream to the same nursery lakes where they hatched in order to spawn, and then die shortly thereafter. Upon their death, all of the marine-derived nutrients, including the elevated $\delta^{15}\text{N}$ signal, are released to the nursery lake. The elevated $\delta^{15}\text{N}$ signature in the salmon tissues is preserved in the sediments and thus provides an indirect proxy of past salmon abundances.

Finney et al. (2000) tracked past salmon fluctuations in five Alaskan nursery lakes (including two control lakes with no salmon) using a multiproxy approach that included (1) diatoms, to infer nutrient levels; (2) cladoceran concentrations, to infer food availability for the juvenile salmon; and (3) sedimentary $\delta^{15}\text{N}$, as an indirect proxy of salmon abundances. They showed a relationship between salmon abundances and climate in the North Pacific, with greater abundances (as inferred by $\delta^{15}\text{N}$) recorded during periods of warm sea surface temperatures in the Gulf of Alaska (Figure 7). Although climate was identified as an important factor, Finney et al. also showed how overfishing contributed to a lengthy twentieth century collapse of a commercial fishery in one of their study sites. Specifically, the harvesting of salmon in the ocean reduces the amount of carcass-derived nutrient subsidies to the nursery lakes. Lower nutrient inputs into the oligotrophic nursery lakes translates into lower algal abundances and thus lower abundances of zooplankton, which

Figure 7 Sedimentary $\delta^{15}\text{N}$ profiles from the sockeye salmon nursery lakes (Red, Karluk, Akalura, Ugashik, and Becharof) and two control lakes (Frazer and Tazimina) from the Kodiak Island and Bristol Bay region of Alaska. The bottommost panel shows the mean $\delta^{15}\text{N}$ signature for the nursery lakes plotted against the sea surface temperature (SST) from the Gulf of Alaska. Reproduced from Finney BP, Gregroy-Eaves I, Sweetman J, Douglas MSV, and Smol J (2000) Impacts of climatic change and fishing on Pacific salmon abundance over the past 300 years. *Science* 290: 795–799, with permission.

represent a critical food source for the juvenile salmon. The overharvesting of adult salmon in the ocean before they can return to their nursery lake effectively decouples this delicate feedback cycle between nutrients, food availability, and juvenile salmon abundances.

The Finney et al. study illustrated the importance of biovector nutrient subsidies to the salmon nursery lakes. In fact, marine-derived nutrients delivered by biovectors often shape the ecosystem structure and function of many coastal and inland sites. An unfortunate irony is that, in addition to life sustaining nutrients, biovectors can also shunt contaminants to receptor sites, sometimes at concentrations that are detrimental to aquatic life (Blais et al., 2007). This occurs because biovectors typically occupy a high trophic position in the marine food web and thus they biologically accumulate and concentrate contaminants, which can be transferred to recipient ecosystems via waste products and carcasses. Krümmel et al. (2003, 2005) analyzed polychlorinated biphenyl (PCB) concentrations in the sediments from nursery lakes that receive a high return of sockeye salmon. They showed that salmon represent a more potent transport pathway for PCBs relative to atmospheric processes.

Seabirds may be the most globally relevant biovectors because they are found on every continent, often in large colonies of tens of thousands of individuals and some that even number millions. Adopting a similar approach to that developed in the salmon research, Michelutti et al. (2009) examined the impact of a large colony of seabirds on a series of freshwater ponds located near Cape Vera on Devon Island (High Arctic Canada). The study site at Cape Vera is home to 20 000+ Northern fulmars (*Fulmarus glacialis*) that nest on steep-sided cliffs above a small coastal foreland containing numerous freshwater ponds. Using a multiproxy approach, Michelutti et al. showed that the northern fulmars had undergone a climate-induced population increase over the last several decades (as inferred by sedimentary $\delta^{15}\text{N}$) and that contaminants including PCBs and metals such as cadmium can be directly linked to biotransport by seabirds. Biotransported contaminants thus provide an additional, independent means of tracking past seabird population dynamics.

Typically, research on biovector transport focuses on gregarious animals that congregate in dense and populous communities because large numbers are required for the biotransported nutrients and other substances to have any significant ecological effect. However, one large animal, such as a whale, can have a similar effect to thousands of smaller-bodied species. Douglas et al. (2004) used a multiproxy approach to track the influence of Thule Inuit whaling activities on the ecology of Arctic ponds. The Thule people were the first whalers in the High Arctic, and they would butcher their kills on land, often near freshwater ponds. This is evidenced by the numerous bowhead whale bones that often litter the landscape near former Thule camps. Douglas et al. recovered a sediment core from a pond on Southeastern Somerset Island that predated Thule occupation. They were able to track the arrival of the whalers over eight centuries ago by showing an enrichment in sedimentary $\delta^{15}\text{N}$ (bowhead whales are enriched in $\delta^{15}\text{N}$) and a coincident shift in diatom assemblages, namely, the rise of *Pinnularia balfouriana*, a moss epiphyte that increased in abundance as mosses increased in abundance in response to nutrient increases from the flensed whale carcasses.

The effects of biovector transport on aquatic ecosystems include changes to water quality, nutrient availability, contaminant exposure, and biological assemblages. In order to document the multiple impacts that biovectors have on lakes and ponds, the inclusion of multiple proxies that provide independent, but related, ecological information is required.

Conclusions

The last several decades have witnessed tremendous advancements in the field of paleolimnology with respect to proxy development, the application of new proxies to environmental problems, and statistical techniques for analyzing complex datasets. These advancements have paved the way for multiproxy approaches, which are becoming increasingly popular because they offer many advantages over more traditional single-proxy studies. These advantages include the ability to (1) obtain holistic environmental reconstructions, (2) identify both environmental stressors and associated ecological effects, (3) resolve competing hypotheses of environmental change, (4) track

differential limnological responses within spatially separated lake habitats, and (5) track multiple environmental stressors.

Multiproxy studies in paleolimnology are now the norm. This is driven in part by the increasing complexity of environmental issues facing freshwater ecosystems, and society in general. The combinations of threats from many well-known stressors including climate change, eutrophication, and acidification are having heretofore unpredicted and often complex effects, and newly discovered limnological threats such as Ca depletion loom large. Multiproxy studies present several challenges, the biggest of which include coordinating all participants involved and a willingness and capacity to synthesize large and complex datasets. Carefully designed and well-executed multiproxy studies have the potential to address newly emerging environmental issues all within a paleolimnological framework.

Visible and Infrared Spectroscopical Applications

Introduction

Infrared (IR) radiation was first discovered by Herschel in the nineteenth century, but it was not until late in the nineteenth century that the term 'infrared' was introduced (Herschel, 2000). From its first discovery to spectroscopic applications that make use of the particular characteristics of IR radiation, another century passed. In fact, it was not until the 1950s when analytically sophisticated devices made their way from research laboratories to industry. IR spectroscopic techniques have since been improved and today applications are manifold.

Visible (VIS) and IR spectroscopies utilize a wide range of the electromagnetic spectrum between 25 000 and 1 cm⁻¹ (0.38–1000 µm). Because of the wide range covered and the difference of interactions between radiation and different materials, the IR region is commonly subdivided into near-infrared (NIR; 0.78–3 µm), mid-infrared (MIR; 3–50 µm), and far-infrared (FIR; 50–1000 µm) regions. Because of their relatively simple, reliable, and nearly maintenance-free instrument setups, VIS and IR spectroscopies are widely used in industrial and scientific research applications that commonly include process monitoring and quality control (Davis and Williams, 1997).

Because of the advantages of VIS and IR spectroscopy over other methods, applications of these techniques are also becoming popular in Quaternary and environmental sciences. Pioneering work utilizing the VIS and NIR regions in paleolimnology include quantitative inferences of lake-water pH, total phosphorus (TP) concentration, and total organic carbon (TOC) concentration (Korsman et al., 1992; Nilsson et al., 1996); inferences of carbon, nitrogen, phosphorus, and diatoms in lake sediments (Malley et al., 1996, 1999, 2000); and assessment of the origin and spatial variability of sediments (Korsman et al., 1999). The MIR region has long been utilized for the identification of different mineral phases (Farmer, 1964, 1974) and to date commercial and computerized spectral libraries exist for almost any chemical compound (e.g., Sadler standard spectra). Pioneering work on both lacustrine and marine sediments utilizing the MIR region includes qualitative and quantitative analyses of different mineral phases (Bertaux et al., 1996, 1998; Chester and Elderfield, 1968; Rosén et al., 2010, 2011a; Sifeddine et al., 1994; Vogel et al., 2008).

Theoretical Background

IR spectroscopy utilizes the fact that molecules absorb specific frequencies characteristic of their three-dimensional structure, atomic weight, and bond type. Spectra in the visible-NIR

(VNIR) region absorb radiation between polar bonds of light atoms such as those in the first period (row) of the periodic table. The characteristic VNIR absorbance spectrum of a sample arises thus from a combination of fundamental C–H, O–H, N–H, and S–H vibrations. In VNIR spectroscopy (VNIRS), overtones of molecular vibrations are primarily measured (Figure 1). As the number of combinations and overtones in VNIR spectra are large, spectra from complex materials can contain a high number of overlapping bands from different bonds, making direct interpretation from these spectra difficult (Bokobza, 1998). Multivariate modeling is therefore commonly applied to extract chemical information from complex VNIR spectra (Figure 2). VNIRS is primarily used today for analyzing samples that contain organic and hydrogen bounds such as carbohydrates, cellulose and hemicellulose, proteins, and lipids (Davis and Williams, 1997; Osborne and Fearn 1988). Lake sediments constitute a mixture of these and other VNIR-active substances derived from organisms formerly living in a lake and its catchment and IR spectroscopy is therefore of interest for sediment studies (Meyers and Ishiwatari, 1993).

In contrast to VNIR, spectra in the MIR region directly monitor fundamental vibrations (stretching, rocking, bending, wagging, and twisting) that are dependent on the mass of the atoms, three-dimensional structure, and degree of symmetry of the molecule (Figure 2). Spectra in the MIR region measured from solid, liquid, or gas-phased samples contain very detailed structural and compositional information on both organic and inorganic sample compounds. A great advantage of the MIR over the VNIR region is that compound-specific absorption bands are usually better separated, facilitating visual interpretation of the spectra, as well as identification and quantification of MIR-active substances. The MIR region is divided into the group frequency region (1500–4000 cm⁻¹) and the fingerprint region (400–1500 cm⁻¹; Figure 1). Absorbance in the fingerprint region is generally due to intramolecular phenomena and thus is highly specific to each compound. The specificity in the fingerprint region makes it easier to identify specific components or use computerized data searches within reference libraries. The vibrational bands in the group frequency region are generally broader and are typically due to functional groups (e.g., CH, CH₂, CH₃, –OH, C=O, –CHO, N–H).

Quantification of different compounds from MIR spectra is possible because absorbance directly relates to concentration of the compound of interest according to the Beer–Lambert law:

$$A = \varepsilon Cl \quad [1]$$

where ε is the molecular absorptivity, C is the concentration, and l is the path length. However, peak integration, as a

Figure 1 Example of spectra and molecular vibrations for some common organic and inorganic bond types in (a) the visible and near-infrared region and (b) the mid-infrared region. The spectra (red line) are an example of a sediment sample from Lake Ohrid (Macedonia/Albania), with total inorganic carbon (TIC) and total organic carbon (TOC) concentrations of 3% and 1.5%, respectively. Loading plots (bottom blue curves) show the relative contribution of different wave numbers to the partial least squares regression (PLSR) models for biogenic silica (BSi), TIC, and TOC using a large number of sediment samples (879–3164) of varying age (0–340,000 years) and from very diverse lake settings in Antarctica, Argentina, Canada, Macedonia/Albania, Siberia, and Sweden (Figure 3; Rosén et al., 2011a). High values indicate wave numbers positively correlated to the Y variable and low values indicate wave numbers negatively correlated to the Y variable. For better visualization, spectra have been shifted vertically from their common baseline by adding a constant value to each spectrum. Reproduced with permission from Bruker Optics.

means of quantifying a certain compound, is only possible when overlapping with other MIR-active compounds in the same spectral region can be ruled out. In the case of marine or lacustrine sediments that are mixtures of a wide

variety of MIR-active compounds, multivariate data analysis and calibration need to be applied in order to quantify certain compounds of interest (see the section 'Theoretical Background').

Figure 2 Flow chart documenting work flow for qualitative and quantitative analysis of sediment samples using visible and infrared spectroscopy.

Sample Preparation and Statistical Approaches in VIS and IR Spectroscopy

VIS and IR spectroscopy are quick methods that only require minor sample pretreatment. Prior to analysis, samples need to be (freeze-)dried, ground to particle size in the fine-silt fraction (2–63 μm), and homogenized in order to achieve material suitable for reproducible and representative measurements (Figure 2). Dried and ground sediment samples can be measured using VNIR devices without any further sample preparation. Small sample quantities (ca. 100 mg) are placed in sample cups and measured manually, depending on the instrument setup, by placing the sample into the IR beam or automatically using multi-samplers. In contrast to VNIRS, measurements in the MIR region, commonly by means of Fourier transform infrared spectroscopy (FTIRS), require dilution of the sample material by IR transparent substances such as KBr, at an appropriate ratio. This is because FTMIR measurements on solids can produce very high absorbance and thus noisy data. For sediment samples, a commonly applied ratio of sediment to KBr is 0.02, that is, 10 mg sediment mixed with 500 mg KBr. Similarly to VNIRS, powdered and mixed samples are placed in sample cups and measured either manually or automatically using multi-samplers. If a multi-sampler is used, up to 500 samples can be analyzed in 1 day.

If samples are measured on different IR spectrometers, but results need to be compared afterward, special attention has to be paid to ensure that the analytical environment and measurement conditions (constant laboratory temperature and humidity, vacuum, etc.) are as similar as possible. When these criteria are matched, calibrations developed for one instrument can be transferred to another and vice versa. This has been tested for Bruker FTIR spectrometers operating under

vacuum (Bruker IFS 66v/S) and nitrogen cooled (Vertex 70) conditions. Measurements between both instruments are comparable, despite different detector and instrument setups.

As combinations of absorption bands seen in the VIS to MIR regions are typically broad, leading to complex and overlapping spectra, it can be difficult to assign distinct features to specific chemical components. One way to extract qualitative and quantitative information on sediment components is through multivariate data analysis, such as principal component analysis (PCA) and partial least squares regression (PLSR) (Martens and Næs, 1989). Prior to multivariate analysis, the spectra need to be baseline-corrected. A commonly used technique is multiple scatter correction (Geladi and Dabakk, 1995; Geladi et al., 1985). The aim of this method is to remove variation in spectra caused by between-sample scatter variations in order to linearize the spectra and eliminate variation caused by noise. The remaining variation is only supposed to contain chemical information about the samples. Spectra in the MIR region can also be baseline-corrected by setting to zero certain wave numbers that do not contain chemical information. PCA on the baseline-corrected VIS to MIR spectra can yield a first impression on major changes in sediment composition, outliers can be identified, sediment horizons where large changes occur can be assessed, and the spectral region and sediment properties that cause most of the variation can be identified.

Based on a first evaluation using PCA, other, more time-consuming and expensive techniques can be applied to selected sections for more detailed multiproxy analyses. After calibration using multivariate regression techniques such as PLSR, spectral information can be used to quantitatively assess compositional changes of the sediment (e.g., Rosén et al., 2011a). Reliable calibrations can be established using an

internal calibration. An internal calibration is, for instance, a calibration for a stratigraphically connected sediment succession (e.g., Vogel et al., 2008) or a regionally confined surface sediment sample set (e.g., Rosén et al., 2010). In such an attempt, preferably at least 100 (VIS–MIR) spectra are regressed against conventionally analyzed sediment properties such as organic carbon, inorganic carbon, and biogenic silica (BSi) concentrations. The calibration is statistically evaluated by using cross-validated coefficient of correlation (R^2_{cv}) and root mean squared error of prediction based on cross-validation ($RMSEP_{cv}$). The most important spectral regions used by the model can be assessed by using the loading values from the PLSR (Figure 1). For optimal performance of the model, there should be a good correlation between the important spectral region used by the calibration model and the actual spectral fingerprint of the compound of interest. When a robust calibration model is established, it can be applied in a rapid and cost-efficient way to infer concentrations of important sediment components solely from spectral information, by using only small sediment quantities. This approach can be of great advantage when very long sediment sequences, several hundred meters in length, need to be analyzed in high resolution (Rosén et al., 2010; Vogel et al., 2008).

VNIRS Applications for the Qualitative and Quantitative Inference of Sediment Properties

To date, a number of applications exist that utilize the advantages of measurements in the VNIR region to extract environmental information and information on sediment composition. VNIR applications for the quantification of sediment constituents such as TP, total carbon (TC), and total nitrogen (TN) exist and show good statistical performance compared to data measured using conventional techniques (r^2 's of 0.99 for TP, and >0.93 for TC and TN; Malley et al., 1999, 2000). In contrast, inferences of carbonates and the amount of diatoms/BSi using VNIRS lack similarly good correlations, with r^2 values of 0.8 for the inference of carbonate content (Malley et al., 1999) and r^2 values ranging from 0.54 to 0.42 for the inference of diatom amounts/BSi concentrations (Hahn et al., 2011; Malley et al., 1999). This is primarily because carbonate and BSi molecules are not excited by radiation in the VNIR region and thus direct relations between absorbance and concentrations of these components cannot be established.

Besides quantitative inference of particular sediment components, NIR spectral information has been used to describe changes in sediment composition in a more qualitative way. Korsman et al. (1999) used NIR spectra to show the influence of catchment properties on surface sediment quality in a small lake in northern Sweden. The sediment properties could be explained only to a minor extent by water depth and organic matter concentration, and the NIR spectra revealed the importance of different types of land use and inlets for the sediment properties. A study by Rosén et al. (2000) documented the impact of catchment vegetation along an altitudinal gradient on compositional changes in surface sediment composition. In this study, a surface sediment set consisting of 76 samples was collected along an altitudinal (hence climatic) and vegetation gradient. The results show that surficial

sediments from lakes situated at different locations along the gradient could be distinguished and that a statistically significant relationship is observed between measured altitude of the lakes and altitude inferred from VNIR spectra. The altitude transfer function was converted to July temperature and successfully applied to a Holocene sediment sequence from an alpine lake in northern Sweden. The inferred temperature from the VNIRS altitude model showed similar trends to inferred July temperatures derived from chironomids, diatoms, and pollen. However, similar to transfer functions based on biological indicators, the correlation between the VNIR spectral information and climate is not direct, but probably an effect of qualitative changes in sediment composition, depending on climate-controlled catchment dynamics.

The initial ideas by Nilsson et al. (1996), Korsman et al. (1999), and Rosén et al. (2000) and the fact that a substantial part of organic carbon in small headwater lakes may originate from catchment sources led to the application of VNIRS that aims at inferring TOC concentrations of lake water using sediment archives (Rosén, 2005). It is unlikely that there is a direct relationship between NIR spectra of sediments and TOC concentration of ambient lake water. Instead, the correlation between VNIR spectra and lake-water TOC concentration is more likely an effect of correlated source-related compositional changes of organic matter deposited at the bottom of the lake. As a first attempt, Rosén (2005) could show the potential of VNIRS to infer lake-water TOC in different lake settings. The study demonstrates the impact of Holocene changes in catchment dynamics on the inferred lake-water TOC values in boreal, tree-line, and alpine lakes and thus emphasizes the role of catchment properties for lake-water TOC concentration (Battin et al., 2009). In close correspondence to the study by Korsman et al. (1999), it was demonstrated that organic carbon concentrations in lacustrine sediment only explained a minor part of the VNIRS-inferred lake-water TOC. This is because VNIRS spectra contain more detailed information on organic matter (Figure 1) enabling, for instance, characterization and identification of humic substances in lacustrine sediment (e.g., Belzile et al., 1997). The application of VNIRS lake-water TOC has been further tested and applied to lakes affected by human impact (Cunningham et al., 2011; Rosén et al., 2011b) and has been used to assess the effect of mire development, permafrost dynamics, and tree-line changes in Sweden, Finland, Russia, and Canada (Jones et al., 2011; Kokfelt et al., 2009; Reuss et al., 2010; Rosén and Hammarlund, 2007; Rosén et al., 2009; Rouillard et al., 2011; Rydberg et al., 2010).

Pigments and their degradation products in lacustrine sediment can be applied to infer past primary productivity (Leavitt et al., 1994). Analysis of pigments commonly requires wet chemical sample preparation and high-performance liquid chromatography (HPLC) and is thus time-consuming. A simpler means of analysis might be through VNIRS. Chlorophyll *a*, its derivatives, and degradation products exhibit a reflectance minimum close to 675 nm in the VIS region. Das et al. (2005) and Wolfe et al. (2006) found a strong correlation between the area of the reflectance trough in the 650–700 nm region and summed concentrations of chlorophyll *a*, its derivatives, and degradational products. Further applications of VNIRS to assess pigments yielded promising results, which are,

of course, not as detailed and precise as pigment inferences using HPLC, but on the other hand open up the possibility of obtaining a rough idea of historical changes in lake trophic status in a nondestructive and rapid way (Keatley et al., 2011; Michelutti et al., 2010).

VNIRS has also been applied to ornithogenic (bird-deposited) sediments to reconstruct the extent of penguin populations (Liu et al., 2011). Synthetic mixtures of penguin guano and weathered soils demonstrated that reflectance, in particular in the NIR regions, increased with guano concentration. PCA and linear mixing modeling were applied to spectral data in order to quantify the amount of penguin guano in downcore lacustrine sediment samples. Based on this approach and by assuming that the amount of penguin dropping input to lake sediments reflects the size of the penguin population, the size of penguin populations on the Ardley Islands, Antarctica, during the past 2700 year was reconstructed (Liu et al., 2011).

VNIR spectroscopy is commonly used in the industry for *in situ* process monitoring. A great advantage is that the measurements are done directly on the moving sample in the process stream without any sample pretreatment. *In situ* scanning using visible light (380–730 nm) was also tested on laminated, siliciclastic sediments from proglacial Lake Silvaplana in the eastern Swiss Alps (Trachsel et al., 2010). Scanning was performed at 2 mm resolution to assess a correlation between spectral information and climate variables. By using multiple linear regression, a calibration model was established that explains 84% of the variance of summer (JJAS) temperature during the calibration period 1864–1950. When applied downcore to quantitatively infer summer temperature back to AD 1177, the temperature reconstruction was in good agreement with independent historical and tree-ring datasets that extend back to AD 1500 and AD 1177, respectively. This approach indicates that valuable information on sediment composition can be derived from *in situ* scanning. This implies that VNIRS can be used as a nondestructive technique to rapidly acquire quantitative paleoenvironmental information in high resolution without tedious sample pretreatment.

MIRS Applications for the Qualitative and Quantitative Inference of Sediment Constituents

Due to the very confined character of absorption bands (Figure 1), the MIR region offers the opportunity to provide detailed qualitative and quantitative information on a variety of organic and inorganic sedimentary constituents. Early MIR spectroscopy (MIRS) applications were developed for the detection and quantification of a variety of amorphous and crystalline mineral phases, such as opal, quartz, kaolinite, and carbonates in deep-sea sediment and consolidated sedimentary rocks from different depositional sources (Chester and Elderfield, 1968, 1973; Chester and Green, 1968; Ji et al., 2009; Mecozzi et al., 2001). Quantification of mineral phases in these studies has been based on single peak absorbance/transmission calibration by regressing absorbance in phase-specific regions onto concentration by using synthetic sediment mixtures. This approach was found to perform well only if other phases absorbing in the same spectral regions are absent (Chester

and Elderfield, 1968; Chester and Green, 1968; Mecozzi et al., 2001).

An early attempt to use the MIR technique in paleolimnology was to quantitatively assess quartz, kaolinite, gibbsite, and amorphous silica concentrations in sediment (Bertaux et al., 1996, 1998). The approach was based on end-member modeling of MIR spectral information from synthetic multicomponent sediment mixtures. The technique was subsequently used in a number of environmental reconstructions using lake sediment (Bertaux et al., 1996; Wirrmann et al., 2001, 2006). Another attempt to extract quantitative information on BSi, TOC, and total inorganic carbon (TIC) from MIR spectra of lake sediment was introduced by Vogel et al. (2008). In this approach, data on property concentration, measured by conventional analytical techniques, was regressed onto MIR spectral information by applying PLSR. The results indicate that calibrations for stratigraphically connected sediment successions can be developed and applied downcore (Vogel et al., 2008, 2010). In order to test the general applicability of these calibrations independent of a stratigraphic connection, larger datasets from lakes worldwide were included into the PLSR calibrations. The results showed that BSi, TOC, and TIC can be assessed independently by using universally applicable calibrations based on samples from around the world (Figure 3; Rosén et al., 2010, 2011a). MIRS also enables very detailed studies of important sediment components such as BSi (Fröhlich, 1989; Gendron-Badou et al., 2003; Schmidt et al., 2001) and allows for rapid purity control of BSi samples prior to stable isotope analysis (Swann and Patwardhan, 2011).

MIRS has furthermore been proven useful for the characterization of specific organic substances in lake sediments. In particular, studies aiming at deciphering the composition and abundance of humic and fulvic acids in lacustrine (Belzile et al., 1997; Calace et al., 1999) and marine sediment (Braguglia et al., 1995; Calace et al., 2006; Mecozzi and Pietrantonio, 2006) produced promising results. Moreover, diagenetic/degradational changes of humic acids that, for example, show loss of carboxylic and nitrogen-containing groups may be identified from MIRS spectral information (Calace et al., 2006). Due to the wealth of information on organic and inorganic sedimentary components in the MIR region, it is more than likely that other important constituents found in lacustrine sediment can also be qualitatively and quantitatively assessed using MIRS. Due to small sample size and simple preparation and measurement setups, these applications could significantly contribute to studies aiming at deciphering past climatic and environmental changes over very long (Ma) time scales and/or in very high temporal resolution, for example, annually laminated sediments. Apart from applications aimed at identification and quantification of specific components in lacustrine sediment, MIRS has also been applied to track changes in environmental variables. Based on similar ideas to VNIRS (Rosén, 2005; Rosén et al., 2000), MIRS has been applied to assess past tree-line and lake-water TOC changes (Rosén and Persson, 2006).

In recent years, the development of FTIRS microscopy devices has made it possible to assess component-specific spectra of components identified under the microscope. One such example is demonstrated in the study by Rosén et al. (2010) where spectra from single diatom valves were assessed. Thanks to the continuous technical development of FTIR spectroscopy,

Figure 3 Scatter plots showing the relationships between conventionally measured and Fourier transform infrared spectroscopy (FTIRS)-inferred biogenic silica (BSi), total inorganic carbon (TIC), and total organic carbon (TOC) using sediment from ca. 100 Swedish lakes, Lake El'gygytyn (Siberia), Lake Ohrid (Albania/Macedonia), Laguna Potrok Aike (Argentina), Lake Hoare (Antarctica), and Lake Pingualuit (Canada). The inferred values are based on partial least square regression (PLSR) models using the region of 400–3750 cm^{-1} . Reproduced from Rosén P, Bindler R, Korsman T, Mighall T, and Bishop K (2011) The complementary power of pH and lake-water organic carbon reconstructions for discerning the influences on surface waters across decadal to millennial time scales. *Biogeosciences* 8: 2717–2727.

potential applications of the technique also continue to increase. Considering the variety of applications presented in this article, we encourage more researchers to further develop both the VNIRS and FTIRS techniques for applications in marine or lake sediment science.

Introduction

Eolian (windblown) sediments, soils, and paleosols constitute some of the most important components of the Quaternary stratigraphic record. Low-latitude arid or semiarid regions, under the influence of subtropical high-pressure cells, have significant areas of eolian sand (Goudie, 2002; Lancaster, 1995; McKee, 1983). ‘Loess’ is eolian silt that mantles preexisting topography and is thick enough to form a recognizable unit when observed in the field. As much as 10% of Earth’s land surface may be covered by loess, primarily in mid-latitude regions (Pye, 1987). A distinct advantage of eolian sand and loess over other Quaternary sediments is that they can be dated directly, using luminescence methods, requiring only the sediment (Aitken, 1998).

Although eolian sand and loess occupy large areas of Earth’s land surface, eolian sediments are not limited to these areas only. It is now known that many parts of the deep-ocean floor are mantled with long-range-transported (LRT) eolian particles, mostly <10 µm in diameter. In addition, polar ice caps, Greenland and Antarctica, also contain important records of LRT dust. Records of periodic dust deposition onto polar ice can be retrieved from cores that now span much of the middle and late Quaternary.

Soils are naturally occurring bodies that mantle most of the land surface of Earth. Soil geography is a function of the combined effects of climate and vegetation, as well as parent material composition, parent material age, and topography (Birkeland, 1999; Jenny, 1941; Schaetzl and Anderson, 2005). Because of their close links to climate, vegetation, and age of parent material, soils are powerful tools in Quaternary stratigraphy, geomorphology and landscape evolution, archaeology, and paleoclimatology. Soils of the past, called paleosols, are particularly important in stratigraphy, interpreting past conditions of climate or vegetation, and the duration of land surface stability.

Eolian Sand in the Quaternary

Sand consists of mineral particles with diameters >50 µm but <2000 µm. Eolian sand can take the form of dunes or sheets. Dune fields are eolian sand bodies that not only contain many dunes but may also occupy significant areas, on the order of 1000–10 000 km². Some areas of eolian sand in desert basins are so large (on the order of 50 000–100 000 km² or more) that they are referred to as ‘sand seas’ or ‘ergs.’ The largest sand seas in the world are found in subtropical latitudes of Africa, Arabia,

Figure 1 Map showing the global distribution of eolian sand, whether active or stabilized. and Australia ([Figure 1](#)). The main reason for this is that these regions are situated under subtropical high-pressure cells, where subsiding air suppresses precipitation and deserts develop. The large sand seas in these areas are found mostly in topographic basins, where sand accumulates from surrounding uplands. Lancaster reviews the origin, ages, and paleoclimatic

significance of low-latitude sand seas. Large sand seas, both active and stable, also occur in the mid-latitudes of Asia, South America, and North America. Although mid-latitude regions are usually not as dry as the areas under subtropical high-pressure cells, the winds are usually stronger and large sand bodies can accumulate if there is a sufficient supply of

Figure 3 Photographic gallery of inactive or mostly inactive dunes in the (a) Nebraska Sand Hills, USA; (b) northern Sinai Desert, Egypt; (c) Mojave Desert, California, USA; (d) New Providence Island, Bahamas; and (e) Brandon Sand Hills, Manitoba, Canada. All photographs by D.R. Muhs, USGS.

sand. Sun and Muhs review the origins of mid-latitude dune fields. At still higher latitudes, dune fields are very small, but they are widespread over North America and Eurasia. Most high-latitude dune fields are related, either directly or indirectly, to the abundance of sand supplies that are ultimately linked to glacial sources. Wolfe reviews the origins of high-latitude dune fields.

Dune fields are significant for understanding past climates of the Quaternary for at least two very important reasons. One is that degree of dune activity is, to a great extent, a function of the amount of vegetation cover, which in turn is often conditioned by overall moisture balance (Lancaster, 1995). In many low-latitude dune fields and some mid-latitude dune fields, eolian sand is currently active (Figure 2). Active dunes are those that lack a vegetation cover and whose particles are transported on a seasonal to daily basis. In contrast, in a climate with a positive moisture balance, a stabilizing vegetation cover can be sustained. Inactive or stable dunes usually have a vegetation cover and experience little or no movement (Figure 3). Thus, in areas where inactive dunes occur, eolian sediments often reflect a past period of greater-than-present aridity or vegetation disturbance (e.g., from fire, overgrazing, etc.). Furthermore, stratigraphic sections that contain alternations of eolian sand and buried soils may record shifts between relatively arid and relatively humid climates.

A second reason for dunes being important for Quaternary paleoclimates is that they are sensitive indicators of wind

direction. The geomorphology of dunes is variable (Figure 4). Some dunes have a crescentic form (barchan, barchanoid-ridge, and parabolic dunes), others have a linear form (linear, longitudinal, or sief dunes), and still others have a multiple-ridged form (star dunes). The wind regimes associated with barchan, linear, and star dunes are reasonably well established (Fryberger and Dean, 1979; Lancaster, 1995; Livingstone and Warren, 1996). Thus, stabilized dunes can yield past wind directions if the original dune form is well preserved. Some studies have shown dune geomorphic evidence of multiple shifts in past wind directions that reflect changes in synoptic-scale climatology.

Loess in the Quaternary

Loess occupies large areas of China, Central Asia, Russia, Europe, Argentina, New Zealand, and North America. Most loess is concentrated in mid-latitude regions (Figure 5), and its texture and mineralogy make it one of the most favorable parent materials for agricultural soils. Indeed, loess-derived soils produce crops that support literally millions of people in Asia, South America, North America, and Europe. Loess is dominated by silt-sized particles (50–2 μm diameter), although most loess contains smaller amounts of sand and clay. This particle size distribution, along with slight carbonate cementation, produces interparticle binding that makes loess stand in vertical bluffs in exposures (Figure 6).

The importance of loess in Quaternary studies is that it is one of the few terrestrial deposits that may contain nearly complete records of glacial-interglacial cycles. A classical model of loess is that it forms primarily during glacial periods, when continental ice sheets or valley glaciers produce silt-sized rock 'flour' by grinding. This silt is in turn transported and sorted by fluvial processes as outwash, deposited on floodplains, and ultimately entrained by the wind. It is now also known that nonglacial processes also produce silt-sized particles. Nevertheless, even in areas known to contain nonglacial loess, it appears that the most favorable times for loess entrainment, transportation, and deposition are during glacial periods. Mahowald et al. (1999) have pointed out several factors, including generally drier climates, decreased vegetation cover, stronger winds, and a decreased intensity of the hydrological cycle, that enhance loess and dust transport during glacial periods. The latter factor can account for loess or finer grained dust staying in suspension longer than is the case under nonglacial climates. Thus, Quaternary stratigraphic studies have shown that loess is characteristic of glacial periods in most regions (Figure 7).

Another important characteristic of loess for Quaternary paleoclimatic studies is that it can aid in reconstruction of past atmospheric circulation. Because loess is deposited directly by the wind, it is one of the most straightforward paleoclimate proxies that can be used to test atmospheric general circulation models. Loess properties that can be used to reconstruct paleowinds include decreasing thickness and particle size downwind from a source. In some regions, such as North America, paleowinds generated from loess deposits are at variance with modeled atmospheric circulation for the last glacial period (Muhs and Bettis, 2000). In other regions, such as South America, loess patterns are in good agreement with model reconstructions (Muhs and Zárate, 2001).

Fine-Grained Eolian Sediments in the Quaternary

Far-traveled dust (also called aerosolic dust and LRT dust) is one of the most interesting and best studied sediments in the Quaternary paleoclimate record. LRT dust consists largely of particles $<10\ \mu\text{m}$ in diameter; thus, it has some overlap with loess, and indeed some LRT dust is probably the distal, or farthest traveled, component of loess. Aerosolic or LRT dust is archived principally in three kinds of settings: (i) deep-sea sediments, (ii) lake sediments, and (iii) ice caps. Rea reviews the important records of LRT dust deposition in deep-sea sediments. One distinct advantage of studying LRT dust in deep-sea sediments is that the eolian record can be placed directly within the global oxygen isotope stratigraphic record (Figure 7). There are important records of long-distance transport of aerosolic dust to the Pacific Ocean (largely from Asia) and the Atlantic Ocean (largely from Africa) throughout much of the Quaternary (Rea, 1994). Aerosolic, or LRT, dust is important for a number of reasons:

1. it is an indicator of source-area aridity;
2. it is an important tracer for atmospheric circulation;

3. it has the potential for altering Earth's heat balance (either cooling or warming) via effects on radiation transfer; and
4. it can provide iron and other nutrients to primary producers, such as phytoplankton, in the world's oceans. LRT dust can also be an important component of soils and may contribute significantly to soil fertility.

Soils and Paleosols in Quaternary Records

Soils are found on virtually every part of the Earth's land surface, other than areas covered by water bodies (lakes and rivers), glacial ice, or steep mountain slopes. The evolution of soil morphology is a function of the interacting factors of climate, organisms (plants and animals), relief or topography, parent material, and time (Birkeland, 1999; Jenny, 1941). There is a rich diversity of soils in North America (Figure 8), and it is the close association of soils with climate, vegetation, and age of parent material that gives soils their utility in Quaternary stratigraphic studies. Soils form in part by weathering of the host sediment or rock. Bettis reviews this topic in an article on weathering profiles. McFadden reviews soil

morphology in Quaternary studies and Kemp discusses soils at a finer scale elsewhere in this encyclopedia.

Soil morphology proceeds along evolutionary pathways that differ from climate to climate (Figure 8). In the humid climates of the mid-latitudes, relatively fine-textured parent materials (fine-grained till, loess, alluvium, or lacustrine sediment) yield soil B horizons that tend to become thicker, more clay-rich, and redder over time (Figure 9). In contrast, in semi-arid and arid regions, where precipitation is too low for chemical leaching, carbonates build up over time (Figure 10). Thus, increasing overall carbonate content, and thickness and complexity of carbonate horizons are characteristic of soil evolution over time in dry regions (Gile et al., 1966).

Evolution of soils through time can be applied to Quaternary stratigraphic studies. Considerable success has been achieved in

this application by the career-long efforts of Birkeland (1999). A hypothetical example of the use of soils in stratigraphy, specifically valley-to-valley stream-terrace correlation, illustrates the approach. In Figure 11, Valley A has four terraces with better developed soils on successively higher terraces, whereas Valleys B and C each have only three terraces. Soil morphology indicates that the first terrace of Valley A is missing in Valley B and the third terrace of Valley A is missing in Valley C. This simple example can be extended to valley-to-valley correlation of glacial sequences, colluvial deposits, eolian sands, marine terraces, and ancient lacustrine deposits. The approach is reliable and inexpensive and allows stratigraphic correlation when materials suitable for numerical dating are absent.

Paleosols are soils of the past (Figure 12). What constitutes a paleosol has been the subject of considerable debate, and

diverse points of view are presented in Morrison (1998). Morrison proposed that 'geosol' be used to denote buried paleosols and succeeded in placing this term in the North American Stratigraphic Code. Despite this, the term has not gained general acceptance by many Quaternary stratigraphers and pedologists, and the term 'buried paleosol' has continued to be used by most investigators.

Two important aspects of paleosols are that they are key stratigraphic markers and can be used in paleoenvironmental interpretations. As a stratigraphic marker, a buried paleosol's uppermost boundary provides the contact between geologic deposits of two different ages (Figure 13). As such, paleosols are often crucial in interpreting Quaternary stratigraphy. It is important to remember, however, that many buried paleosols are remnants of once-thicker soils, and in some cases, they have been eroded completely (Figure 13). Nevertheless, many Quaternary sections contain buried paleosols with sufficient preservation to make paleoenvironmental interpretations possible. A hypothetical example of such a situation is shown in Figure 14, where the present arid climate has produced a modern soil with a well-developed Bk horizon. Below this is a buried paleosol that lacks a Bk horizon but has a thin Bt horizon, suggesting a wetter past climate that was sufficient to leach carbonates and allow clay illuviation. Still deeper is a buried paleosol with an even thicker Bt horizon, which could suggest a very humid climate and/or a much longer period of pedogenesis than that of the paleosol immediately above it. Finally, at the base of the hypothetical section is a buried paleosol with a Bk horizon, suggesting a time when the climate was arid, as is the case today. Thus, the overall sequence represents a history as follows:

- an arid climate, much like today;
- a long humid period, much wetter than today;
- a shorter, humid period; and
- the present arid climate.

This kind of application of soil morphology to paleoclimatic reconstruction has been particularly fruitful in loess sequences, where paleosols are often well preserved (Figure 15).

Conclusion

Eolian sediments (sand, loess, and LRT or aerosolic dust) are important archives of the Quaternary geologic and paleoclimatic record. They are extensive on Earth's surface at all latitudes and can be dated using luminescence methods that require only the sediment. Unlike many Quaternary sediments, eolian deposits are direct indicators of atmospheric circulation. Furthermore, they are robust indicators of past aridity. In addition, fine-grained eolian sediments may have effects on climate itself, both directly, in terms of radiative transfer via albedo effects, and indirectly, caused by fertilization of primary producers that affect the global carbon cycle.

Soils and paleosols are also key components of the Quaternary stratigraphic record. They cover a majority of the Earth's land surface and are closely linked to climate, vegetation, and the length of time that a surface or deposit has been exposed. Paleosols, soils of the past, are important stratigraphic markers in the Quaternary record. Under conditions of good preservation, paleosols contain rich records of climate history.

Introduction

Paleosols are soils ‘formed in a landscape of the past,’ often but not always buried, which provide crucial evidence on past land surfaces and environments. Quaternary paleosols were recognized in the nineteenth century, if not earlier. In 1866, A.H. Worthen described a soil horizon separating glacial till from overlying loess in central Illinois, United States, later named the Sangamon Soil. The term ‘soil’ was poorly defined in this early work, however, and often referred to sediments rich in organic matter rather than to well-defined soil profiles as we recognize them today. In Russia, [Dokuchaev \(1883, pp. 94–95, 162\)](#) described soils buried by dune sand and slope-wash. By the 1920s and 1930s, pedologists increasingly drew much more specific analogies between surface soil profiles and buried paleosols. Since that time, Quaternary researchers in many parts of the world have used such analogies to infer paleoclimate from paleosol morphology. Finally, in the late twentieth century, it was recognized that the great loess–paleosol sequences of China and other regions represent the only terrestrial records of Quaternary climate change comparable in length and completeness to those available from marine cores.

Paleosols still play a crucial role in Quaternary studies, both as stratigraphic markers and as sources of paleoclimatic data. More recent work has revealed the complexity of paleosol genesis, however, often leading to qualification of earlier interpretations. Quaternary paleosols, especially those in loess successions, rarely represent a simple sequence of parent material deposition followed by top-down pedogenesis. In fact, many paleosols reflect the interaction of sedimentary and pedogenic processes, with pedogenesis occurring in actively accumulating parent sediments. Thus, the morphological features of many Quaternary paleosols reflect not only the climate under which they formed, but also parent material sedimentation rate relative to the rate of soil-forming processes. Finally, recent decades have seen increasing research on paleoenvironmental reconstruction based on magnetic or geochemical proxy data extracted from paleosols.

Issues of Terminology

The term ‘paleosol’ is applied to buried soils, soils that were once buried but are now exhumed by erosion and form the modern surface soil, and even relict soils that preserve evidence of ancient soil-forming environments but have never been buried. The focus of this article is primarily on buried paleosols. The North American Stratigraphic Code uses the term ‘geosol’ (introduced by [Morrison, 1967](#)) for formally defined pedomorphological units, which must be buried paleosols, but this term has seen little use elsewhere.

Where an existing soil is buried by a thin increment of sediment, subsequent surface soil development may extend downward into the buried paleosol. The two overlapping profiles are then referred to as either a ‘composite soil’ or ‘welded soils’; ‘pedocomplex’ is also used to refer to this phenomenon. In some settings, a composite paleosol may diverge laterally into two or more discrete paleosols. Such divergence may be observed over short distances in alluvial or hillslope deposits; for example, a single thick surface soil may split into several distinct surface and buried soils with distance down a single footslope. Over greater distances, multiple buried soils in source-proximal loess can converge into a single composite paleosol at distal sites.

Most researchers restrict the term paleosol to horizons representing a significant period of surface exposure, and significant alteration from the original condition of the parent material. However, there are no simple, widely agreed-upon criteria for the threshold of pedogenesis above which a paleosol can be identified.

This article uses the horizon designations adopted by US pedologists, including A (surficial horizons of organic matter accumulation), E (eluvial horizon below the A, often light colored), and B (subsoil horizons).

Recognition of Paleosols

Analogy with surface soils remains the essential type of evidence used in identifying buried paleosols. Macro- and micromorphological features diagnostic of specific pedogenic processes are often most convincing, but multiple lines of evidence are generally needed to identify paleosols that represent a significant period of surface exposure and pedogenesis. For example, some fine-grained sediments, including unoxidized glacial tills, quickly develop a form of blocky structure on exposure in road- or streamcuts, which might be mistaken as evidence for more protracted pedogenesis. A sequence of horizons in which the structure varies in a pattern common to many surface soils (e.g., a downward transition from fine granular to blocky structure that coarsens with depth) provides more convincing evidence for a significant period of pedogenesis, and microscopic evidence of extensive clay illuviation or mineral weathering probably indicates thousands of years of surface exposure. Geochemical, mineralogical, or rock-magnetic data can be valuable in characterizing the degree of parent material alteration by weathering and other pedogenic processes, but in themselves are rarely useful in paleosol recognition. Few paleopedologists would accept the identification of a buried soil simply on the basis of measurements such as magnetic susceptibility, in the absence of morphological evidence visible in the field.

Some paleosols are so similar in appearance to modern soils that there is little debate over their pedogenic origin. This is particularly true when a dark-colored A horizon is preserved, a common characteristic of Holocene paleosols in dune sand, loess, tephra, or alluvium (Figure 1). Dark-colored beds of sedimentary origin do occur in alluvium, but generally can be identified by lack of pedogenic features or the presence of undisturbed sedimentary structures. In paleosols without a dark-colored A horizon, strongly expressed pedogenic structure and color may still allow general consensus on the presence of a buried soil (Figures 2 and 3(a)–3(c)), but there is often disagreement on both the assignment of specific horizon labels (A, B, etc.) and the relationship of the paleosol to modern soil taxa. These issues are even more contentious in the case of weakly expressed, light-colored paleosols. Sediment that accumulated on vegetated surfaces, such as loess, often displays evidence of root growth or animal burrowing but this is rarely considered sufficient for identification as a paleosol (Figure 3(b)).

Figure 1 Paleosols with well-preserved, dark-colored A horizons. (a) Buried soils in a loess exposure in western Nebraska, United States. The most prominent dark band (marked by arrow) is the A horizon of the Brady Soil, which separates late Pleistocene and Holocene loess units across much of the central Great Plains region. Lighter bands above the Brady Soil are weak soils developed during the more humid intervals of the Holocene, separated by increments of more rapidly deposited loess. (b) Dark buried A horizon within dune sand in eastern Inner Mongolia, China.

Another problem arises when paleosols are identified in stratified sediments in which individual beds have highly contrasting colors and/or textures. This commonly leads to disagreement over whether particular horizons are pedogenic or sedimentary in origin. To some extent, this is a false dichotomy, since the boundaries of pedogenic horizons may tend to develop at lithologic discontinuities that influence soil water movement and related pedogenic processes.

Exhumed paleosols are generally only recognizable where they can be traced into the subsurface. This is the case across large areas of the midwestern United States outside the limits of the last glaciation (Marine Isotope Stage (MIS) 2). The Sangamon Geosol formed during the last interglaciation (MIS 5) and the subsequent transition back to glacial conditions during MIS 4. It is buried in many places but has been exposed by erosion on sideslopes and in effect forms the surface soil there. As discussed below, relict paleosols are clearly identifiable only where their morphology records paleoenvironmental conditions far different from those of the present.

Paleosols as Stratigraphic Markers and Numerical Dating of Paleosols

Paleosols by their nature mark former land surfaces. If a paleosol contains horizons that typically take thousands to tens of thousands of years to develop, then the surface it formed beneath was eroding or aggrading quite slowly, if at all. Thus, significant portions of the time represented by an entire stratigraphic column may be compressed into the paleosol profile.

Figure 2 Profile of the Sangamon Geosol in southern Illinois, formed in Illinoian (MIS 6) glacial till, and buried by loess of the last glaciation (MIS 3 and 2). Although a dark A horizon is not preserved, the reddish brown Bt horizon and overlying light-colored E horizon form a profile closely analogous with modern forest soils of the region. Illinoian till (C horizon) overlies an older paleosol visible near bottom of photo.

Figure 3 Paleopedology of the Luochuan loess section, Chinese Loess Plateau. (a) Photo of part of the section, with paleosols S4 and S5 marked. (b) Close-up of paleosol S1, which has reddish brown color similar to many B horizons, but micromorphological characteristics of a bioturbated A horizon. (c) Close-up of loess below S1 (L2), with displays abundant biopores indicating accumulation on a vegetation-covered surface. (d) Interpretation of paleosols S1 through to S4 in terms of their closest modern analogs and environment of formation, based mainly on inference of pedogenic processes from micromorphology. Adapted from Bronger A and Heinkele T (1989) Micromorphology and genesis of paleosols in the Luochuan loess section, China: Pedostratigraphic and environmental implications. *Geoderma* 45: 123–143.

Such relatively stable surfaces marked by well-developed paleosols are often of great interest within Quaternary deposits. In glaciated regions of North America and Europe, each major glaciation in effect created a new land surface underlain by glacial till, outwash, loess, and related deposits. That surface was then exposed to pedogenesis for tens of thousands of years before being buried by sediments of the next glaciation. Through this process, paleosols can potentially mark the boundaries of each glacial–interglacial cycle. In reality, subglacial erosion must often remove paleosols that are directly overridden by ice, since they are only preserved in some of the regions that have experienced multiple glaciations. In the central United States, the Sangamon Geosol is extensively

preserved within and beneath loess deposits beyond the ice margin of the last glaciation (MIS 2). This paleosol is also often present beneath glacial sediment from MIS 2 in Illinois, near the southern limit of the MIS 2 ice sheet. In Michigan, Wisconsin, and Minnesota, states of the northern United States covered by thicker and longer-lasting glacial ice during MIS 2, there are few reported localities where the Sangamon Geosol is preserved under younger glacial sediment. Prominent paleosols in the loess successions of China and Central Asia also mark global interglacial periods, based on the fairly sparse age control now available, mainly from magnetostratigraphy.

In theory, paleosols that form stratigraphic markers may be time transgressive. For example, as continental ice sheets grew

during the last glaciation, soils farther south would have been buried later. However, age control on paleosols rarely has sufficient resolution to clearly demonstrate time transgression. Uncertain age control also makes it difficult to test the assumption that most strongly expressed paleosols form during interglacial periods, and especially during short intervals of peak interglacial warmth. In some cases, geochronological data clearly disprove this assumption. For example, a prominent paleosol in the Palouse Loess of eastern Washington, United States, formed during the last glaciation, based on the ages of bracketing tephras (**Figure 4**).

This example illustrates the importance of numerical dating methods in the interpretation of paleosols. The most straightforward application of numerical dating is to bracket the time of soil formation, by dating deposition of both the paleosol's parent material and the sediment that buries it. Techniques useful for this purpose include luminescence dating; radiocarbon dating of detrital wood, charcoal, or other material; and tephrochronology. The duration of pedogenesis, and in certain cases the numerical age of overlying sediments, can be estimated from measurements of cosmogenic nuclides (beryllium-10, aluminum-26, etc.) within a paleosol. These nuclides are either produced *in situ* within soil minerals or produced in the atmosphere and added to the soil in precipitation. Radiocarbon dating of soil organic matter in paleosols generally underestimates the age of the parent material, at least

slightly overestimates the age of overlying sediment, and provides little information on the duration of pedogenesis. Nonetheless, this technique has provided valuable information in settings where other dating methods are not applicable or produce questionable results.

Inference of Paleoenvironments from Paleosol Morphology

Surface soils display regional or local patterns of variation that can be used to infer the paleoenvironments in which paleosols developed. Such analogies can provide information on paleoclimate, paleoecology, and even paleohydrology.

Long-recognized regional and global patterns of soil geography are especially useful in the interpretation of paleosols. For example, as first clearly documented by **Dokuchaev (1883)**, soils on stable upland summits in temperate grasslands commonly display relatively thick, dark colored, highly bioturbated A horizons, while temperate forest soils typically have thin A horizons underlain by light-colored eluvial horizons. **Bronger (1991)** provides a comprehensive overview of changes in soil macro- and micromorphology across the forest to grassland transition in Eurasia and North America. These changes can potentially be used to identify former vegetation boundaries as recorded by regionally extensive paleosols.

Figure 4 Aggradational pedogenesis in loess of the Palouse region, northwestern United States. Former A horizons burrowed by insects (cicadas) are buried by additional loess sedimentation, and are transformed into calcium carbonate- and silica-cemented B horizons. In this case, aggradational pedogenesis produced a prominent composite soil with two peaks of carbonate and silica content. Development of this major paleosol occurred within the last glaciation, not under interglacial conditions, because it is bracketed by tephra from the Mount St. Helens (MSH) volcano. Tephra are labeled: MSH-C (erupted about 43 000 years ago), and MSH-S (about 15 400 years ago). Reproduced from McDonald EV and Busacca AJ (1990) Interaction between aggrading geomorphic surfaces and the formation of a late Pleistocene paleosol in the Palouse Loess of eastern Washington State. In: Kneupper PLK and McFadden LD (eds.) *Soils and Landscape Evolution. Proceedings of the 21st Annual Binghamton Symposium in Geomorphology*, pp. 449–470. Amsterdam: Elsevier, Geomorphology.

Secondary calcium carbonate accumulation and clay illuviation can also provide evidence of the paleoenvironments in which buried soils formed. In well-drained soils, secondary carbonate accumulation is much more common in regions where evaporation exceeds precipitation than in more humid areas, and the depth to secondary carbonate decreases with decreasing rainfall. In temperate Eurasia, illuvial clay pedofeatures are generally believed to be limited to forest-covered regions and the forest-steppe transition zone, where leaching of base cations has been sufficient to allow clay dispersion and translocation. This pattern has often been disputed in North America, however, on the basis of clay-rich B horizons in dry regions.

Weathering, oxidation, and reduction can also leave evidence of past environments of soil formation. Significant depletion of weatherable minerals and formation of kaolinite-rich clay mineral suites is generally associated with warm humid climates of the tropics and subtropics, although deep weathering may also occur in temperate regions given enough time. In fact, the most convincing examples of relict paleosols are soil profiles displaying mineralogical evidence of intense weathering in regions that are now relatively dry and/or cool. Poorly drained soils commonly display features indicative of episodic or sustained reducing conditions. In parts of the midwestern United States where the Sangamon Geosol formed in glacial sediments, it can be assigned to drainage classes through morphological and mineralogical analogies with surface soils. Finally, distinctive soil faunal burrows and root traces may help identify the ecosystems within which paleosols developed.

These spatial patterns and their relation to paleoenvironmental factors are often difficult to quantify. Nonetheless,

there are many good examples of qualitative or semiquantitative paleoenvironmental reconstruction using paleosol morphology. In the classic Chinese loess section of Luochuan (Figure 3), neither the Holocene soil (S0) nor the upper three Pleistocene soils (S1 through to S3) display micromorphological evidence of significant clay translocation. However, illuvial clay is present in many of the older paleosols. The exact climatic contrast recorded by this upward change in pedogenic regime is difficult to specify, but it clearly suggests that precipitation during interglacial periods was greater before MIS 9 (correlated with S3), allowing more effective leaching of base cations and perhaps sustaining forest or forest-steppe vegetation. Soils S0 through to S3 are all interpreted as having formed under drier conditions and steppe vegetation. Consistent with this interpretation, other researchers have found illuvial clay features in S1 near Xi'an, in the southeastern Loess Plateau where modern precipitation is greater than at Luochuan (Figure 5).

One of the most important complications in the paleoenvironmental interpretation of paleosols is the time dependence of soil morphological evolution. Boardman (1985) considered the case of interglacial paleosols in the United States and Europe, which are often more strongly developed and redder than soils formed during the Holocene. This could indicate that past interglaciations were warmer than the present one, but probably also reflects a greater duration of pedogenesis. In the subtropics of central Mexico, a sequence of paleosols formed in tephra provides evidence of the time dependence of soil morphological evolution. Paleosols with a shorter duration of pedogenesis have the chemical, mineralogical, and morphological characteristics of andosols (volcanic

Figure 5 Pedosedimentary reconstruction of the development of S1, the paleosol representing the last interglacial period, at a site near Xi'an in the humid southeastern Loess Plateau, China. (a) Photo of S1 near Xi'an. (b) Diagram from Kemp et al. (1997), illustrating the reconstructed sequence of pedogenic and sedimentary events (right), and the supporting micromorphological data (upper left).

ash-derived soils with low bulk density, high organic matter, and abundant allophane), but with increasing duration of pedogenesis mineral weathering and clay illuviation become more extensive until gross morphology resembles Luvisols (forest soils with clay-enriched B horizons) that were previously interpreted as evidence of more humid climate.

Aggradational Pedogenesis and Postburial Alteration of Paleosols

Traditional conceptual models of soil genesis often assume top-down soil formation below a static land surface. In contrast, many paleosols, especially those in loess, volcanoclastic sediment, alluvium, or colluvium, developed beneath an episodically or continually aggrading land surface. In essence, soil-forming processes competed with, and in some cases were strongly influenced by, sedimentation. This phenomenon has previously been called 'upbuilding,' and 'cumulization' refers to the specific case in which sedimentation causes overthickening of one or more horizons. Here the term 'aggradational pedogenesis' is used to emphasize the active roles played by both sedimentation and pedogenic processes in the upward growth of soil profiles. Soils formed by aggradational pedogenesis form part of a continuum, from sedimentation too rapid for any significant pedogenesis, to top-down pedogenesis beneath a completely stable land surface. Stratigraphic successions in which recognizable paleosols are separated by less altered sediment represent variation along this continuum over time, in response to changing rates of both sedimentation and pedogenesis.

The concept of aggradational pedogenesis implies that paleosol horizons may have a complex history, reflecting initial formation just below the ground surface followed by burial at increasing depths over time. As a simple example, consider a highly bioturbated A horizon with relatively high organic matter content and granular structure, that was buried by several tens of centimeters of loess or alluvium. With much less fresh input, the organic matter content of this horizon could be depleted by decomposition, resulting in a lighter color. Blocky structure might develop under the lower frequency of bioturbation and wetting and drying cycles at the horizon's new depth, although granular aggregates could still be preserved within the larger blocky peds. Either clay illuviation or secondary carbonate accumulation could occur within the former A horizon. In effect, the A horizon would be transformed into a B horizon through shallow and/or slow burial. This transformation can explain why many paleosols have been interpreted as lacking A horizons, in fact, aggradational pedogenesis should probably be the preferred explanation unless there is clear evidence of truncation by an erosional event. Former B horizons can also be transformed, for example, by superimposition of secondary carbonates on illuvial clay.

Research in several regions of the world supports this model of aggradational pedogenesis. A well-documented example is illustrated in [Figure 4](#). Insect burrows that formed within or just below surficial A horizons were buried at a greater depth by loess sedimentation, and then overprinted by calcium carbonate and silica cementation. This resulted in B horizons characterized by relict A horizon features, such as the insect burrows. In the central Great Plains, United States, the

Sangamon Geosol is often capped by what appears to be an unusually thick, dark-colored A horizon, with well-preserved granular structure and other evidence of soil faunal activity ([Figure 6](#)). As early as 1951, James Thorp recognized that much of this horizon is in fact a loess unit deposited on top of the existing Sangamon Geosol profile in the early stages of the last glaciation. The existing Sangamon A horizon was built upward by slow accumulation of this loess. The loess unit responsible for aggradation of the Sangamon land surface is now identified as the Gilman Canyon Formation, which accumulated mainly during MIS 3, based on radiocarbon and luminescence dating. One key piece of evidence supporting this interpretation is provided by soil stratigraphy along transects from sites near loess sources to more distal localities. Near loess source areas, the Gilman Canyon Formation is several meters thick and contains two or more buried A horizons ([Figure 6\(a\)](#)). With greater distance downwind, the loess unit thins and the A horizons merge, resulting in the appearance of a single unusually thick A horizon at the most distal sites ([Figure 6\(b\)](#)).

Micromorphological investigations can often provide crucial evidence in reconstructing the pedosedimentary history of Quaternary deposits such as loess–paleosol sequences. This approach is discussed elsewhere in this encyclopedia, but one instructive example is shown in [Figure 5\(b\)](#). The development of the S1 paleosol in the southern Loess Plateau of China is inferred to have included three stages, beginning with a relatively humid phase with slow loess deposition and clay illuviation. Two subsequent stages marked by increasingly dry conditions and more rapid loess sedimentation, during which secondary carbonate features were superimposed on illuvial clay deposited during the earlier more humid phase. Another noteworthy example is the micromorphology-based reconstruction of sedimentary events and climatic changes affecting a complex polygenetic paleosol in Iowa, United States.

The possibility of aggradational pedogenesis must be taken into account when paleosols are used as stratigraphic markers. Consider a buried paleosol that marks the boundary between the deposits of two glaciations. If only top-down pedogenesis is recognized, the upper boundary of sediment assigned to the older glaciation should be placed at the top of the paleosol profile. If, however, this profile has been built upward by loess deposition as it developed, its upper horizons may in fact contain sediment from the interglacial period or from early stages of the younger glaciation. In that case, pedogenesis may well have obscured the actual upper boundary of sediment assignable to the older glaciation. This complication is well-established in the case of the Sangamon Geosol in the central United States, and is probably not uncommon elsewhere.

Aggradational pedogenesis also has implications for the paleoenvironmental interpretation of paleosols. If the overthickening of an A horizon by loess deposition (e.g., [Figure 6](#)) is not recognized, it could be inferred that the entire underlying soil profile were formed in a cool, humid grassland environment, similar to areas where thick, dark A horizons are found today. From a broader perspective, aggradational pedogenesis can produce features in paleosols that are difficult to explain when using simple surface soil profiles as analogs. These can include overthickened A or B horizons, B horizons with multiple peaks of clay or secondary carbonate, and the occurrence

Figure 6 Sangamon Geosol and overlying Gilman Canyon Formation loess on the Great Plains. (a) Section close to loess sources, in which Gilman Canyon Formation is thicker and contains two recognizable buried A horizons, the lower of which is darker. (b) Section relatively far from loess sources, in which Gilman Canyon Formation is contained within a single overthickened A horizon at top of Sangamon Geosol. Total Gilman Canyon Formation thickness is indicated by the vertical bar in both parts, with question mark indicating uncertainty of its lower boundary.

of both secondary carbonate and illuvial clay in the same B horizon. Some surface soils contain features best explained by aggradational pedogenesis, and recent insights on that process from paleopedology may well be applicable in explaining surface soil genesis.

Transformation of A horizons into B horizons, and superimposition of secondary carbonates over illuvial clay can both be considered forms of postburial alteration in paleosols, a widely recognized but poorly understood phenomenon. Possible forms of postburial alteration include loss of organic matter, compaction, precipitation of secondary carbonates in formerly carbonate-free horizons, and formation or destruction of redoximorphic features. Some of these processes may in fact be most effective when burial is shallow, as in aggradational pedogenesis. For example, an A horizon buried in the well-oxidized shallow subsurface may lose organic matter more rapidly than one buried quickly to a much greater depth, where either reducing conditions or infrequent wetting inhibit decomposition. Alternatively, compaction generally increases with overburden thickness.

Postburial alteration can easily lead to misinterpretation of paleosols. For example, many paleosol horizons in the Chinese loess superficially resemble reddish brown B horizons, but in at least some cases have micromorphological features characteristic of bioturbated A horizons. Presumably, the color of these horizons has been altered by postburial loss of organic matter (Figure 3(b)).

Magnetic and Geochemical Proxy Data from Quaternary Paleosols

Recent decades have seen extensive efforts to extract paleoclimatic reconstructions from the rock-magnetic properties and

stable isotope geochemistry of paleosols. Pedogenesis clearly affects the rock-magnetic properties of soil horizons, although these properties are also affected by parent material provenance and sorting during transport. The most commonly measured rock-magnetic property is magnetic susceptibility, the degree of magnetization induced in a material by a magnetic field. On the Chinese Loess Plateau, magnetic susceptibility is greatly enhanced in paleosols, but interpretations remain controversial. Various studies suggest that magnetic susceptibility is related to both paleoprecipitation and duration of pedogenesis. In contrast, loess-derived paleosols in some other regions display depletion of magnetic susceptibility relative to unweathered loess. Taken together, these observations suggest that much more information on the processes that alter rock-magnetic properties during pedogenesis is required, before these properties can be considered broadly applicable, unambiguous proxies of paleoclimate.

Ratios of the stable isotopes of carbon, oxygen, and other elements can be measured in paleosol organic matter and pedogenic carbonates. The theory and methodology of reconstructing paleoenvironments from isotopic records are beyond the scope of the chapter, but the great potential of stable isotope data extracted from paleosols can be summarized as follows. Stable carbon isotopes in both soil organic matter and pedogenic carbonates often record variation in the relative abundance of plants using the C_3 , C_4 , and Crassulacean acid metabolism photosynthetic pathways, which generally represents a response to climate change; changing atmospheric C isotope ratios and moisture stress or other factors influencing photosynthesis also may be recorded. In shallow horizons, C isotopes in carbonates are sensitive to soil characteristics affecting exchange of soil carbon dioxide (CO_2) with the atmosphere. Oxygen isotope ratios in carbonates can be used to reconstruct past changes in air temperature and atmospheric

circulation. Oxygen isotope ratios in pedogenic iron oxides can provide similar information, and may be less prone to post-burial alteration, but have received little attention in Quaternary paleopedology.

Here we emphasize the need for interpreting isotopic records from soils in light of the complexities of paleosol genesis described above. For example, when isotopic analyses have been carried out on organic carbon collected from a range of depths down through a paleosol, it is important to know whether this sequence can be interpreted as a simple time series. This could clearly be the case for a soil developing through aggradational pedogenesis. It would not be a safe assumption in the case of top-down pedogenesis, even if radiocarbon ages from organic matter systematically increased with depth, because such depth trends may simply record slower carbon cycling at greater depths. Landscape-scale soil stratigraphic work, combined with high-resolution luminescence dating at selected sites, can potentially resolve this issue.

Future Directions in Quaternary Paleosol Research

It is now clear that the stratigraphic and paleoenvironmental interpretation of Quaternary paleosols is a problem of great complexity, because of aggradational pedogenesis and the dependence of soil properties on time as well as environmental factors. New cosmogenic nuclide and luminescence dating methods hold great promise as tools in resolving both of these sources of complexity, but must be integrated with the methodology and insights developed over more than a century of research on paleosols and their modern analogs.

Glossary

Antiferromagnetic: Anything that is not magnetic because of equal and opposite sources of magnetism within the material.

Chronosequence: A group of soils in which time is the predominant soil-forming factor. Parent material, climate, biota, and topography do not vary significantly among the soils of a chronosequence.

Diamagnetism: Weak magnetization due to the orbital motion of electrons.

Ferrimagnetism: A form of ferromagnetism in which the electron spin is opposite but unequal.

Ferromagnetism: A form of magnetism in which there is strong interaction among atoms in a crystal.

Frequency-dependent susceptibility: The difference in induced magnetization at two frequencies that differ by tenfold.

Loess: Wind-blown silt that is deposited and stabilized so that it becomes soil parent material.

Magnetic susceptibility: A measure of the temporary induced magnetization of a sample placed in a weak magnetic field.

Oxyhydroxides: A broad classification of minerals found in soils and sediments that are a combination of iron, aluminum, oxygen, and hydroxyls.

Paramagnetism: Magnetism arising from the spin of electrons in an atom.

Parent material: The starting material from which soil develops. It may be residuum or transported material.

Remanent magnetization: The permanent magnetization remaining after a sample is removed from a magnetic field.

Introduction

Measurement of magnetic properties of natural materials (soils, sediments, and rocks) is teaching Earth scientists about the Earth and Earth processes. The purpose of this article is to discuss what magnetism is and how magnetic measurements are used to learn about soils and sediments.

What Is Magnetism?

Magnetism is a force produced by a magnetic field. The force acts at a distance from the source of the magnetic field. For ferromagnetic materials, such as those containing certain compounds of iron, nickel, and cobalt, the interaction is particularly strong. Unlike electric charges, magnetic 'charges' always come in pairs, called poles, which have opposing charges. In a typical magnet, the magnetic force from a given pole strongly attracts the opposite pole of another magnet and repels the similar pole. The most common application of this characteristic is the use of a compass to determine direction.

The Chinese were probably the first to discover that an iron needle, when rubbed against a special rock known as a 'lode-stone' pointed in a north–south direction when freely suspended. In 1600, William Gilbert, the personal physician to Queen Elizabeth I, published the first scientific study of magnetism in a book entitled *De Magnete* (On the Magnet). In 1821, Hans Christian Oersted, a Danish scientist, discovered that an electric current in a wire produced a magnetic field. André-Marie Ampère determined that magnetism was a force between electric currents. He found that two parallel electrical currents flowing in the same direction attracted each other, and

two parallel electrical currents flowing in opposite directions repelled each other.

In space, in the Sun and in the Earth's core, electric currents produce magnetism. In the Earth, movement of the molten iron–nickel core creates a dynamo that produces the magnetic field observed at the surface of the Earth (Figure 1). To first approximation, the magnetic field at the surface of the Earth is the same as the magnetic field of a bar magnet with one pole near the geographic North Pole and the other near the geographic South Pole.

This article is primarily concerned with magnetism on a much smaller scale, namely the magnetism of certain minerals, and the use of the magnetic properties of these minerals to better understand earth processes and earth history. On this much smaller scale, elements and minerals possess three kinds of magnetism: diamagnetism, paramagnetism, and ferromagnetism. In each case, the source of the magnetism is the spin of each electron around its axis and the rotation of the electrons around the nucleus of an atom. The magnetic moment of an element is the sum of the spin magnetic moment and orbital magnetic moment.

Diamagnetism is the normal response of any material to an applied magnetic field. The response is transient, meaning the magnetization disappears when the applied field disappears. The magnitude of the response is small, and because of this diamagnetism has little value in environmental magnetism. For purely diamagnetic material, the orientation of the spin and orbital magnetic moments cancel each other, resulting in a zero magnetic moment. If the spin and orbital magnetic moments do not cancel each other entirely, the atom has a permanent magnetic moment and is said to be paramagnetic. In the presence of an applied magnetic field, a paramagnetic

Figure 1 The model Earth. Surrounding the solid Earth is the atmosphere and hydrosphere. The thin active zone at the surface, upon which all terrestrial life depends is the pedosphere that is a few meters thick. The outer part of the solid Earth below the pedosphere is the 100 km thick, rigid crust, the lithosphere. Below the crust is the mantle. The upper portion of the mantle is the soft, plastic (deformable) asthenosphere, which varies in thickness but is generally thought to be about 200 km thick. The remainder of the 2600 km thick mantle is solid. The mantle surrounds the core, which has a radius of 3500 km, the densest part of the solid Earth. It is believed to consist of two parts, a solid inner core and an outer liquid core. It is the motion of the liquid portion of the core that produces the Earth's magnetic field.

material also acquires an induced magnetization, and the paramagnetic response is about 1000 times greater than the diamagnetic response. This is strong enough to make paramagnetic minerals of interest to Earth scientists.

In contrast to the transient magnetization of diamagnetic and paramagnetic materials, ferromagnetic materials possess a permanent or remanent magnetization. Various forms of remanent magnetization are explained later in this article. The permanent magnetization results from the interaction and alignment of electrons between different atoms in a mineral lattice. The lattice is the arrangement of atoms in a crystal. The most common natural ferromagnetic materials are oxides and oxyhydroxides of iron, cobalt, and nickel. There are different types of ferromagnetism. In ferrimagnetic materials, the aligned spins form two interpenetrating lattices with opposite alignment but different strengths. This produces a net permanent magnetization. In antiferromagnetic materials, the two lattices have the same strength so the net magnetization should be zero. However, defects in the crystal structure (lattice defects) or a slight tilting of the two lattices with respect to each other (spin canting) can lead to antiferromagnetic material with a net magnetization. Dunlop and Özdemir (1997) present many details on these concepts of magnetization.

The most important naturally occurring magnetic minerals are magnetite, maghemite, and hematite. All are iron oxides that may contain varying amounts of titanium that substitutes for iron during mineral formation. Thus, technically, we should be writing about magnetite and titanomagnetites, and about hematite and titanohematites but for simplicity, we use the simpler terms. Magnetite is found in igneous, metamorphic, and sedimentary rocks and in the unconsolidated sediments that arise from the decomposition and erosion of these rocks. Among soil scientists, magnetite, especially coarse-grained magnetite, is considered an inherited mineral that is part of soil parent material.

Hematite gives soil a red color and is a common weathering product of other iron-bearing minerals. Goethite is another weathering product that contributes brown and yellow-brown colors to soil. Both are weakly magnetic compared to magnetite and maghemite but are typically more abundant in soils than either of the more magnetic iron oxides. The red color imparted to soils from hematite implies strongly weathered parent material and is often a clue that such soils will also have strong magnetic properties due to the presence of magnetite or maghemite.

Maghemite is strongly magnetic (like magnetite) and common in soils. Unlike magnetite, it is considered a secondary iron oxide, produced in soils and sediments by chemical changes to inherited minerals. Its abundance and distribution in soil profiles is used to indicate intensity of soil formation and of weathering of parent material.

Magnetic Measurements

The simplest magnetic measurement is magnetic susceptibility, which is defined as the proportionality constant between the induced (paramagnetic) magnetization produced by a weak magnetic field and the applied field itself. The magnetic susceptibility is related to the concentration and grain size of ferromagnetic materials in a sample. The magnetic susceptibility is determined by placing a small (<10 g) sample in a weak uniform magnetic field with strength (H) and measuring the magnetization per unit volume (M) acquired by the sample. The volumetric magnetic susceptibility of the sample (κ) is the magnetization acquired per unit field (eqn [1]).

$$\kappa = M/H \quad [1]$$

In the MKS (meters, kilograms, seconds) system, volumetric susceptibility (κ) is dimensionless because both M and H have units of $A\ m^{-1}$ (ampere per meter). Much of the literature on mineral magnetic properties of earth materials uses mass susceptibility (χ), which is volume susceptibility (κ) divided by sample density (ρ ; eqn [2]). In the MKS system, mass magnetic susceptibility has units of $m^3\ kg^{-1}$.

$$\chi = \kappa/\rho \quad [2]$$

The measurement of magnetic susceptibility is a rapid, nondestructive technique that can be used in the laboratory or field with inexpensive instrumentation. The Bartington susceptibility bridge is a commonly used instrument for both laboratory and field studies.

With a Bartington bridge, the magnetic susceptibility can be measured at two frequencies that differ by one order of magnitude; these frequencies are 0.45–0.50 and 4.5–5.0 kHz. The difference in susceptibility at the two frequencies is the frequency-dependent susceptibility (χ_{fd}). Submicron size magnetic particles respond differently to different frequencies than do larger particles, making frequency-dependent susceptibility a simple (indirect) measure of the presence of these fine-grained magnetic particles. Low-field magnetic susceptibility is temperature dependent, and some laboratories are equipped with instruments that can measure κ and χ over a range of temperatures from near absolute zero to 1000 °K. Examples of these measurements and interpretations are given in the next section of this article.

As noted above, ferromagnetic materials can acquire a remanent magnetization that is retained after an external field is removed. Natural remanent magnetization (NRM), anhysteretic remanent magnetization (ARM), and isothermal remanent magnetization (IRM) are three types of magnetizations of use to Earth scientists. The name of each type is based on the conditions under which the remanence was acquired. NRM is the magnetization acquired by a sample through natural processes without application of a laboratory magnetic field. ARM is the magnetization acquired from an applied (direct) magnetic field in the presence of an external alternating magnetic field that is reduced to zero from a predetermined maximum. IRM is the magnetization acquired in the presence of a strong external field at ambient temperature. The response of a sample to a very strong magnetic field can also be studied. At the peak value of the applied field, the sample is magnetized as much as it can possibly be. At this point, the spins are said to be saturated and the magnetization is called the saturation magnetization (M_s). When the applied field is decreased to zero, the M_s decreases but does not fall to zero.

This residual permanent magnetization is the saturation remanence (M_r). Typically M_r and M_s are determined by repeated cycling of the external magnetic field, which produces a hysteresis loop (Figure 2). The direction of the arrows shows that the reverse path is not the same as the forward path as M and H change. The lack of correspondence of the two paths is termed hysteresis. The coercive force (H_c on Figure 2) is the reverse field that is needed to reduce the overall magnetization, M , to zero. The coercivity of remanence (H_{cr}) is the somewhat stronger reverse field that is needed to leave the sample with zero magnetization after the applied field has been removed. These four parameters derived from the hysteresis measurement and the shape of the hysteresis curve provide important information about magnetic grain size and magnetic mineralogy. Like magnetic susceptibility, the remanence measurements are not physically destructive. Thompson and Oldfield (1986) and Evans and

Figure 2 Example of a simple hysteresis loop.

Heller (2003) provide detailed discussions of hysteresis curves. A more sophisticated approach, based on families of partial hysteresis curves known as first-order reversal curves, is described by Roberts et al. (2000).

An important consequence of the nondestructive nature of magnetic measurements is that once these properties have been measured, samples can be subsequently treated to remove specific magnetic fractions prior to making additional magnetic measurements. For example, magnetic properties of soil samples can be measured prior to and following treatment with acids that remove carbonates, and with citrate-bicarbonate-dithionite (CBD) to remove secondary iron oxides and iron oxyhydroxides. In addition, bulk soil samples can be separated into particle size fractions, such as silt ($2\text{--}50\text{ }\mu\text{m}$) or clay ($<2\text{ }\mu\text{m}$), and the magnetic properties of the fractions can be determined.

Interpretation of Magnetic Properties

Soils

Soils are derived from geologic parent materials through biogeochemical processes that act under the influence and control of climate, biota, and topography over time. Mineral magnetic measurements are made on soils and paleosols to determine what the conditions were at the time the soil or soil horizon was formed. This is the 'inverse problem' in which a soil property can be measured and the condition under which the property was formed is inferred from the property. Most often interpretations are made from a group of properties rather than any single property. Mineral magnetic studies of soil are particularly useful when the effect of one of the five soil-forming factors (time, parent material, climate, biota, and topography) can be isolated from the other four.

Soil scientists assume that the C horizon of a soil formed in wind- or water-transported parent material is unaltered (or weakly altered) and is representative of the initial state of that material. This assumption can readily be checked by examining the mineralogy and chemistry of the C horizon. A further assumption is that differences in the amount, kind and vertical distribution of the pedogenic magnetic minerals between the C horizon and other horizons reflect the soil-forming conditions at the sample location. Similarly, soils formed *in situ* from rock have inherited and pedogenic magnetic minerals, and similar interpretations are made on these soils.

Magnetic Susceptibility

In well-drained soils, magnetic susceptibility is often higher in A horizons than in B or C horizons as shown in Figure 3.

The increase in magnetic susceptibility (magnetic enhancement) in the upper soil horizon has been attributed to the conversion of less magnetic or nonmagnetic minerals to more magnetic magnetite (Fe_3O_4) or maghemite ($\gamma\text{-Fe}_2\text{O}_3$) either through rapid oxidation by fire or by slower pedogenic processes. Magnetite and maghemite are the dominant contributors to soil magnetic susceptibility because their magnetic susceptibilities are 10 000 times greater than other commonly occurring iron minerals in soils. Magnetite is the most magnetic naturally occurring mineral. Maghemite has the same

Figure 3 Hypothetical low-field magnetic susceptibility for a soil with three horizons. The total thickness of the profile is 1.5 m. Note the difference in magnetic susceptibility between the original parent material susceptibility (dashed line) and the magnetic enhancement in the A and upper B horizon (solid line).

chemical formula as hematite but is significantly more magnetic because of its crystal structure. It is distinguished from hematite by the Greek gamma before the formula ($\gamma\text{-Fe}_2\text{O}_3$). Among the other common iron minerals in soil are goethite ($\alpha\text{-FeOOH}$), ferrihydrite ($5\text{Fe}_2\text{O}_3 \cdot 9\text{H}_2\text{O}$), and lepidocrocite ($\gamma\text{-FeOOH}$). Goethite, hematite, ferrihydrite, and lepidocrocite are considered 'secondary' soil minerals because they are rarely inherited from the parent material and are usually produced by biogeochemical processes that change the inherited iron minerals into these forms. When magnetite is in large grains ($>1\text{ }\mu\text{m}$) it is typically interpreted to be an inherited mineral in soil. When it is found in small grains, it is interpreted to be a secondary iron mineral.

The minerals that contribute to the enhancement shown in **Figure 3** are usually different than the minerals of the C horizon. Typically, more maghemite is found in the magnetically enhanced horizons than in the C horizon. Of equal interest is that the thickness of the zone of enhancement increases with time and varies with climate. Among the five soil-forming factors, the two with the greatest interest for Earth scientists are climate and time. Magnetic susceptibility enhancement tends to be higher in soils that are more intensely weathered than in less intensely weathered materials. Intense weathering can result from either higher mean annual temperature (MAT) and mean annual precipitation (MAP) or a longer time period of soil formation. Magnetic susceptibility alone cannot be used to clearly separate the factors controlling the intensity of parent material weathering, but it is a useful measurement. **Figure 4** illustrates how increasing the time of soil formation affects magnetic susceptibility enhancement.

The four profiles sampled were developed on the same transported parent material, under the same present MAT and MAP and vegetation, and in the same topographic position along the north coast of California. The main difference between the profiles is the duration of parent material weathering. Such a group of soils is known as a chronosequence. All of the profiles in this chronosequence are not shown in **Figure 4**. The difference in duration of the weathering between each profile is about 100 000 years. The youngest profile (Cabrillo series) is about 100 000 years old and shows an

Figure 4 Vertical distribution of magnetic susceptibility (χ) in a chronosequence formed on marine terrace deposits in northern coastal California. Terraces 1, 2, 3, and 5 are represented by the Cabrillo (1), Cleone (2), Caspar (3), and Fern Creek (5) soils. Reprinted from Singer MJ and Fine P (1989) Pedogenic factors affecting magnetic susceptibility of northern California soils. *Soil Science Society of America Journal* 53: 1119–1127, with permission from the Soil Science Society of America.

enhancement of about 30 units of susceptibility compared to the parent material. The oldest profile shown (the Fern Creek series), which is five times as old, has about 480 units of susceptibility enhancement in the uppermost horizon. The enhancement also extends much deeper into the profile (**Figure 4**). These data illustrate that magnetic susceptibility within a chronosequence changes over time as a function of soil-forming processes.

The exact processes that produce the enhancement and distribution of magnetic susceptibility in soil profiles are not fully known and are subjects of current research. One common soil-forming process is dissolution of inherited minerals and formation of new 'secondary' or 'pedologic' minerals. Weakly magnetic or nonmagnetic iron-containing minerals are common inherited minerals in most soils, and although they have limited solubility, over time, these minerals dissolve, and the iron is released to the soil solution where it may form strongly magnetic secondary minerals such as maghemite. The secondary minerals may remain where they form or be transported to lower horizons. Soluble products of mineral dissolution may also be carried downward as water flows through the soil. Recombination of the dissolution products may form strongly magnetic minerals in subsoil horizons.

CBD treatment of soil samples is used to separate fine-grained from coarse-grained iron-containing minerals. The assumption is that the fine-grained magnetic minerals are formed in soils from transformations of the coarse-grained minerals. **Figure 5** illustrates the effect of CBD extraction on the magnetic properties of a series of paleosols (S-1 to S-5) from the central loess plateau in the People's Republic of China.

This vertical section represents the upper 50 m of a 130-m thick section of buried soils separated by partially weathered loess. The Chinese loess–paleosol sequence has been of great interest to Earth scientists because it is one of the best records of terrestrial climate change yet discovered. In this material, magnetic susceptibility is much higher in the paleosols than in

the loess. Furthermore, the CBD extraction removes most of the low-field susceptibility from the paleosols. This susceptibility has been attributed to fine-grained magnetic minerals although the exact composition of these minerals is still in dispute. These fine-grained iron minerals are formed in soils from inherited coarser-grained minerals. Figure 5 clearly shows that the majority of magnetic minerals in the Chinese paleosols are pedogenic. The magnetic minerals in the loess parent material are inherited and pedogenic. The small amount (compared to the paleosols) of fine-grained pedogenic magnetic minerals which exist in the loess indicate that the loess has either weathered in place after deposition or that it weathered at the source before it was transported to the present site. In our thinking, loess deposition and pedogenesis occur simultaneously at different rates. Thus, it is expected that the loess reflects periods of weaker pedogenesis than the paleosols either because of more rapid deposition of loess or a climate less conducive to soil formation.

The second curve (χ_{post}) also illustrates that the amount of coarse (lithogenic) component is not constant, implying that there are either differences in pre- or postdeposition weathering or different sources of the loess. In either case, the usefulness of CBD in differentiating between the coarse-grained and fine-grained magnetic materials is illustrated in Figure 5.

Figure 5 Total low-frequency magnetic susceptibility (χ_{pre} , black line) and CBD-extractable, (χ_{ext} , red line) and the lithogenic, coarse-textured fraction remaining (χ_{post}) when χ_{ext} is subtracted from χ_{pre} . The frequency-dependent magnetic susceptibility as a function of depth is shown on the far loess and paleosol layers are indicated by green and brown letters. Figure adapted from Vidic NJ, Singer MJ, and Verosub KL (2004) Duration dependence of magnetic susceptibility enhancement in the Chinese loess-paleosols of the past 620 ky. *Palaeogeography, Palaeoclimatology, Palaeoecology* 211: 271–288.

Frequency Dependence

Frequency-dependent susceptibility provides a way of assessing the amount of the finest-grained magnetic minerals in a sample. As noted earlier, submicron size magnetic particles respond differently to different frequencies, making frequency-dependent susceptibility a simple measure of the presence of these fine-grained magnetic particles. The presence of these fine-grained magnetic particles is interpreted to indicate soil development. In Figure 5, the frequency-dependent susceptibility varies like the total susceptibility with the highest values in the soils and lowest values in those parts of the section that are less weathered. This observation provides additional evidence that the soils have more very fine-grained magnetic minerals and that pedogenic processes form these minerals.

In persistent anaerobic environments, magnetite is produced by bacteria, where it occurs in particles that are on the order of a nanometer ($10^{-3} \mu\text{m}$). Biogenic magnetite has not been shown to occur in well-drained terrestrial environments, so it is not expected in most soils. In poorly drained soils that remain saturated or nearly saturated with water for long periods, iron is reduced to mobile Fe^{2+} from immobile Fe^{3+} and is often leached from the soil profile. Under these conditions, there is little magnetic susceptibility enhancement and magnetic mineralogy has limited usefulness in pedogenic studies (Figure 6). The Capay soil series is wetter more frequently than the Yolo and much of the iron has been reduced and removed from the profile, leaving the Capay profile with a lower magnetic susceptibility than the Yolo.

The differences between the magnetic susceptibilities of the two soils can be attributed to the different hydrology of the two

Figure 6 Vertical distribution of low-field mass magnetic susceptibility (χ) in a well-drained soil (Yolo series, dashed line) and a somewhat poorly drained soil (Capay series, solid line) formed on recent alluvium in the Sacramento Valley, CA. Reprinted from Singer MJ and Fine P (1989) Pedogenic factors affecting magnetic susceptibility of northern California soils. *Soil Science Society of America Journal* 53: 1119–1127, with permission from the Soil Science Society of America.

profiles because all other soil-forming factors are the same. The soils have formed in the same age alluvium from the same source under the same climate and biotic conditions. Only their topographic positions differentiate the soil-forming processes at the two sites. Both soils exhibit small enhancement in the uppermost horizon compared to the parent material, but the Capay profile has significantly lower low-frequency susceptibility than the Yolo profile because of persistent wetness. The loss of susceptibility, although not useful in reconstructing past climates, has been used as a method for delineating the extent of wetlands.

Natural Remanent Magnetization, Anhysteretic Remanent Magnetization, and Saturation Isothermal Remanent Magnetization

With the exception of NRM, which is the remanent magnetization of natural samples that have not been exposed to a laboratory magnetic field, all forms of remanent magnetism measure how much magnetization a sample retains after it is removed from a magnetic field. The different forms are used to obtain information about the concentration, mineralogy, and grain size of the magnetic material. Sometimes more than one magnetic property is used to try to separate the effect of grain size from the effect of concentration. For example, the ARM intensity acquired per unit of applied field is designated as the ARM susceptibility (χ_{ARM}). It is particularly sensitive to the presence of small magnetite or maghemite grains. Alternatively, mass magnetic susceptibility (χ) is particularly sensitive to the presence of larger magnetite or maghemite grains. The same is true for SIRM (saturation IRM) which is the IRM acquired in a very strong magnetic field. Thus, the ratio χ_{ARM}/χ or the ratio of the ARM intensity to the SIRM intensity provides information about the relative proportions of fine-grained to coarse-grained magnetite or maghemite. The use of these ratios and others are described in detail in [Evans and Heller \(2003\)](#) and [Maher \(1986\)](#).

Each of these techniques provides information about the minerals that contribute to the magnetic signal from a sample. Climate interpretations made from these measurements are based on our concepts of what kinds of minerals we expect to find, where they occur in soils, their particle size, and magnetic behavior. Interpretations need to be made carefully, because many factors contribute to the measured magnetic property and much is yet to be learned about mineral magnetic properties of soils and sediments.

Conclusions

Naturally occurring magnetic minerals such as magnetite, maghemite, hematite, and goethite are useful for understanding earth materials and for interpreting the climate history of the Earth. Magnetic susceptibility, frequency-dependent susceptibility, various types of remanent magnetizations, and ratios of these quantities are used by Earth scientists to determine the concentrations, compositions, and grain size distributions of naturally occurring magnetic minerals. When these magnetic measurements are applied to soils and sediment, they

provide answers to questions about soil processes and the history of the Earth.

Soil Micromorphology

This article is reproduced from the previous edition, volume 3, pp. 2103–2114, © 2007, Elsevier B.V.

Soil micromorphology is 'concerned with the description, interpretation, and measurement of components, features, and fabrics in soils' at a scale 'beyond that which can be seen readily with the naked eye' (Bullock et al., 1985, p. 9). Although it may include the examination of undisturbed soil aggregates with optical or scanning electron microscopes, it is generally restricted to the study of thin sections using polarizing microscopes. Thin section production requires initial drying and resin impregnation of an undisturbed block of unconsolidated soil material under vacuum. Once hardened, the block is sawn in half and one side polished and affixed to a glass slide. The soil slice is then ground to a thickness of approximately 25–30 µm and, unless microchemical analysis is intended, the polished surface is overlain with a coverslip. Thin section dimensions are typically on the order of 5 × 7 cm, although larger formats (e.g., 13 × 6 cm) are common particularly in archaeological studies.

Soil micromorphology came to prominence with the pioneering work of Kubiena (1938, 1970), who recognized different types of micromorphological fabrics and related them to particular suites of pedogenic processes and soil-forming environments. Although Kubiena's terminology has been superseded by more morphologically based systems (Brewer, 1976; Bullock et al., 1985; FitzPatrick, 1993; Stoops, 2003), the essence of his genetically based approach is still maintained within micromorphological contributions to pedological and paleopedological studies. Soil micromorphology is a valuable technique for the examination of buried, polygenetic, welded, and accretionary paleosols or pedocomplexes, because the recognition of individual or suites of micromorphological features, in tandem with other data, can provide the basis for relatively detailed reconstructions of formative processes and associated paleoenvironmental conditions (Kemp, 1998, 1999). The technique has also been extended to examine materials such as glacial till, lacustrine laminated sediments, and 'cultural' deposits in caves and beneath buildings or archaeological sites (Courty et al., 1989; French, 2003); however, these nonsoil (*sensu stricto*) examples are beyond the scope of this review and are not considered further here.

The aim of this article is to review the use of soil micromorphology in Quaternary paleopedology. It focuses initially on the ways that micromorphological data can aid in the identification of buried soils and also their interpretation in terms of pedogenic processes and environmental controls, notably climate and human activity. It then considers how microstratigraphic associations of features may cast light on changes in intrinsic or extrinsic environmental controls, and it concludes with a discussion of how ordered sequences of pedosedimentary processes can be inferred from micromorphological depth functions within welded and accretionary paleosols or pedocomplexes and used to reconstruct landscape evolution and associated environmental changes. In all cases, it must be realized that soil micromorphology is not a 'magical means of solving pedological problems' (Brewer, 1972, p. 83): there

may be situations in which patterns or variabilities of features are so complex or variable that they are impossible to unravel (Kemp, 1998). Furthermore, it should be regarded as part of a scale continuum of observation and should rarely, if ever, be used in isolation. Utilization of field descriptions and data from other analyses frequently resolves discrepancies, uncertainties, or difficulties regarding micromorphological interpretation.

Micromorphology and the Identification of Buried Soils

Buried soils within sedimentary sequences are normally recognized on the basis of diagnostic horizon sequences and other field criteria. However, in places where the soils are weakly developed, limited in lateral exposure, truncated, or altered by postburial oxidation, groundwater, or loading processes, identification may not be so straightforward. In such cases, the occurrence of a buried soil may be confirmed by the presence of micromorphological features assumed to be of pedogenic origin (e.g., floral or faunal channels, faunal excrements, root pseudomorphs, *in situ* weathered mineral grains, calcitic biospheroids (produced by earthworms), and illuvial clay coatings; Figure 1). It is generally safer to rely on a combination or assemblage of such features, however, because individually they are not necessarily diagnostic of a buried soil. Well-oriented clay coatings, for instance, have been reported from fluvial sediments and glacial tills, whereas diagenetic groundwater concentrations of iron oxides or calcium carbonate may have similar characteristics to precipitates formed in soils (Kemp, 1985). Furthermore, some rapidly formed pedological features, such as channels and excrements, may have limited paleopedological significance where they survive because they may only reflect short-lived vegetation cover and bioturbation at ephemeral aggrading surfaces (e.g., within a floodplain environment), whereas other more resistant features, such as sharply bounded, rounded 'foreign' aggregates, nodules, and fragmented clay coatings (Figure 1(h)), may not be *in situ*, having been eroded from soils formed elsewhere. Depth functions of micromorphological features may support a pedogenic interpretation and also help to differentiate *in situ* soils from transported soil material, provided that similar functions have been established for soils forming at present surfaces.

Paleoenvironmental Significance of Micromorphological Features Within Buried Soils

Once identified, a buried soil is generally interpreted in terms of the pedogenic processes and environments assumed to be currently responsible for that type of soil forming at a present surface. Field and bulk analytical criteria normally form the main bases, although micromorphology has also played a significant role by providing important insights into a number

Figure 1 Micromorphological features that may help to confirm the presence of a buried soil (a–f) or identify a sediment containing reworked soil material (h). of key processes and associated environmental controls, particularly calcite redistribution, clay illuviation, and the generation of cryogenic microstructures. Such an approach is acceptable provided it is tempered by an appreciation of equifinality, namely that some pedofeature–pedogenic process–environment relations may not be unique and that different local and regional combinations of pedogenic processes and/or environmental controls may potentially produce similar micromorphological features (Brewer, 1972). Thus, it is advisable to base overall interpretations on suites of micromorphological features displaying characteristic depth functions supported by field and analytical data.

Calcite Coatings and Infillings

Some of the most common micromorphological features reported from buried soils comprise concentrations of ‘secondary’ calcite crystals within coatings, infillings, impregnative hypocoatings, and nodules (Figure 2) and reflect processes of dissolution, solute migration, and precipitation. Crystal sizes vary considerably (micrite, <10 µm; microsparite, 10–50 µm; and sparite, >50 µm) depending on conditions affecting growth, such as composition of percolating solutions, evaporation rate, and space constraints (Courty et al., 1989). Pure calcite infillings or coatings around grains and along voids often grade into adjacent zones of calcitic impregnation (hypocoatings) of the groundmass (Figure 2(c)). Some coatings, particularly associated with the surfaces of excrements, are composed of needle-fiber calcite (Figure 2(d)) that is thought to form in association with fungal activity (Becze-Déak et al., 1997). Calcitic nodules have a variety of forms ranging from dense, discrete, sharply bounded features to irregular, diffuse segregations (Figure 2(e) and 2(f)) that may even grade into complete micrite-impregnated and cemented groundmasses (Bullock et al., 1985).

The source of the calcite, direction of mobilization, and precipitation mechanism may vary considerably according to climate, parent material, level of biological activity, and groundwater conditions, so assignment of specific environmental significance to individual features is not always straightforward without subsidiary evidence (Fedoroff et al., 1990). For example, upward or lateral migration from a high groundwater table enriched in calcium bicarbonate and vertical leaching from surface to subsurface horizons provide two very contrasting mechanisms (Courty et al., 1989). Surface horizons of soils developed in calcareous parent materials under subhumid or even humid conditions may be decalcified with reprecipitation of leachates occurring lower in the sola. Similar concentrations developed in noncalcareous or weakly calcareous parent materials, however, may reflect vertical leaching processes under more semiarid environments, particularly where there have been inputs of calcareous dust (Becze-Déak et al., 1997). Small-scale changes in pH or partial CO₂ pressures associated with biological activity may also be important controlling influences (Herrero and Porta, 1987). Some compound calcitic depletion–concentration features in paleosols (Figure 2(g)), reflecting localized dissolution–reprecipitation processes (Herrero and Porta, 1987), have been attributed to relatively arid conditions (Kemp et al., 1999, 2001). In such environments, it is also common to find secondary gypsum crystals

within the groundmass (Figure 2(h)) or as individual or clusters of lenticular crystals along voids.

Iron, Manganese, and Aluminum Coatings

Other crystalline pedofeatures reported from soils include (tropical) gibbsite and (hydromorphic) goethite coatings (Stoops, 2003), although periodic anaerobic conditions more often lead to the development of ‘amorphous’ or ‘cryptocrystalline’ ferruginous and manganiferous coatings, hypocoatings, segregations, nodules, and root pseudomorphs, often with associated zones of depletion (Figure 3). Such features in paleosols are invariably taken to imply an imperfectly drained pedoenvironment, although interpretations often need to take into account the potential effects of postburial groundwater oscillations and, in the case of sharply bounded nodules, the possibility of inheritance from the parent material rather than *in situ* formation (Figure 3(d); Courty et al., 1989; Stoops, 2003). Other amorphous isotropic coatings and hypocoatings contain high proportions of organic material, particularly those formed in spodic environments (Stoops, 2003) or where agricultural and urban soils have had large quantities of slurry added.

Anthropogenic Features

Considerable emphasis has been placed by some authorities on the ability to recognize anthropogenic features in thin sections of some buried Holocene soils (Courty et al., 1989; French, 2003; MacPhail, 1998). Often, these features may simply comprise dumped components, such as fragments of pottery and building mortar (Figure 4(a)). Large concentrations of charcoal have sometimes been attributed to deliberate burning during land clearance prior to agricultural development, whereas the presence of ‘exotic’ materials such as carbonized organic matter, turf, ash, and bone (Figure 4(a) and 4(b)) has been used to support the notion that a soil was manured to increase fertility and organic matter content (Carter and Davidson, 1998). Increasing emphasis is being placed on controlled experimental trials using ancient agricultural techniques so as to understand the formation of anthropogenic soil micromorphological features and their preservation after abandonment and burial (MacPhail, 1998). Even then, concerns have been expressed regarding the uniqueness of some microfabrics ascribed to tillage or animal grazing activities (Carter and Davidson, 1998), although the problem of equifinality is not just confined to this area of micromorphology.

The most commonly reported micromorphological indicators of cultivation in buried arable soils are crusts and ‘agricutans’ (Courty et al., 1989) around voids. Such features have been shown to develop when unstable aggregates associated with cultivation at sparsely vegetated surfaces are broken down by intense rainfall. Crusts, typically moderately sorted layered units of clay grading into fine and coarse silt and then into groundmass at their base, get formed following slaking, transport of particles by overland flow, and differential settling at, or close to, the surface during water ponding. These are often subsequently disrupted and mixed by pedoturbation, leaving a random clustering of fragments embedded within the groundmass (Figure 4(c)). Linked to these features are a variety of poorly sorted coarse or silty clay coatings or infillings (agricutans;

Figure 2 Crystalline pedofeatures recorded in thin sections from buried soils. PPL, plane polarized light; XPL, crossed polarized light; scale bars = 500 μm . (c) Fragment of a crust formed by surface slaking; Lanzhou, China. (d) Agricutans (black arrows) comprising coatings of silty clay around voids; Tucumán, Argentina.

Figure 4(d)), which result from rapid translocation of particles in suspension from the slaked surfaces (Courty et al., 1989).

Crusts and silty clay coatings provide classic examples of the need to base micromorphological interpretations on overall context and with reference to all other information. Although they undoubtedly can be associated with arable activity, they primarily reflect a response to slaking of exposed unstable aggregates and therefore may be naturally induced under a range of environments. For instance, the sparse vegetative cover typical of arid and semiarid zones provides soils, often having low organic matter contents, with limited protection from the effects of infrequent and intense rainstorms. Slaking and development of crusts and coarsely textured coatings are therefore common phenomena (Courty and Fedoroff, 1985).

Clay and Silt Coatings

Other silty clay and silt coatings, particularly in mid-latitude European paleosols, are often assigned cold climate significance and are regarded as having formed under relatively non-vegetated surfaces subjected to large inputs of water from snow or ice melt (Fedoroff and Goldberg, 1982). Clearly, such an interpretation is favored where there is subsidiary evidence of cryogenic conditions having existed, either in the field (e.g., ice-wedge casts or periglacial involutions) or in thin sections. Various micromorphological features, similar to ones recorded from present-day Arctic soils and reproduced experimentally in the laboratory by freezing or cycles of freezing and thawing,

have been recorded from Quaternary loess–paleosol sequences. These include banded fabrics, frost-shattered stones, platy structure, and cryoturbated granular aggregates (Figure 5), and they are generally accepted as sound indicators of cryogenic activity and thus periglacial environments (Fedoroff et al., 1990; van Vliet-Lanoë, 1998).

Micro laminated, continuously oriented clay coatings in soils (Figure 1(f)) have been traditionally considered in mid-latitudes as representing the gradual accumulation of clay translocated in suspension under (interglacial) temperate, seasonally dry climates on stable, forest-covered landscapes (Bronger, 1991). Van Vliet-Lanoë (1998), however, maintained that clay coatings in argillic horizons of northwest Europe formed under Late Glacial boreal environments, thus questioning the interglacial status attached to such units. Although Late Glacial interstadial argillic horizons (clay enriched, compared to the overlying horizon) associated with birch forest cover have been reported from southeast England, fine clay illuviation is still largely regarded as an interglacial phenomenon in Britain (Catt, 1996). The previous discussion emphasizes the dangers of assigning too narrow a paleoenvironmental significance to any micromorphological feature in isolation.

Microstratigraphic Relations Within Paleosols

In addition to highlighting individual soil features beyond the range of the human eye that are of paleoenvironmental significance, micromorphology also enables the reconstruction

Figure 5 Cryogenic features recorded in thin sections from buried soils. Plane polarized light; scale bars = 500 μm . (a) Partially disrupted banded fabric, formed by freeze–thaw cycles, comprising alternating subhorizontal bands of silty clay (white arrows) and silt; Lanzhou, China. (b) Frost-shattered flint clast with fitting disaggregated fragments is evidence of the *in situ* nature of the process; Suffolk, UK. (c) Platy structure, formed by ice segregation parallel to the freezing front, comprising platy aggregates separated by horizontal planar voids; Siberia, Russia. (d) Granular aggregates (black arrows) created by cryogenic stresses associated with cryoturbation and solifluction (Van Vliet-Lanoë, 1998), some with cappings of silt grains (white arrow); Bavaria, Germany.

of ordered sequences of pedogenic events from the superposition of components within compound features (Brewer, 1972; Kemp, 1985). Sometimes these microstratigraphic sequences reflect intrinsic changes in the pedoenvironment as the soil develops. For instance, progressive leaching of a calcareous parent material may lead to accumulation of secondary carbonate in the form of calcitic hypocoatings around voids in subsoil horizons. As pH and base saturation drop, conditions may become conducive for clay translocation with consequential accumulation of illuvial clay on top of (and therefore

postdating) the calcitic concentrations (Figure 6(a)). Alternatively, extensive clay illuviation may result in blockage of voids, causing restricted drainage, periodic anaerobic conditions, and development of ferrimanganiferous concentration and depletion features that are superimposed on the clay coatings and infillings (Figure 6(b)).

Perhaps, of more use to Quaternary scientists are microstratigraphic sequences linked to changes in extrinsic, particularly climatic, controls. For instance, some clay coatings in soils from present-day semiarid regions have been interpreted as

Figure 6 Microstratigraphic associations recorded in thin sections from buried soils. Plane polarized light; scale bars = 500 μ m. (a) Illuvial clay (black arrow) postdating a calcitic hypocoating (white arrow) around a channel; Kent, UK. forming during a previous more humid period, and superimposed secondary carbonate features (Figure 6(c)) are taken to reflect a reduction in moisture availability and leaching, with an associated increase in calcareous dust inputs at the surface, in response to drying of climate (Nettleton et al., 1989). In certain situations, compound coatings or infillings containing progressively coarser or finer textured layers (Figure 6(d) and 6(e)) have been interpreted in terms of environmental deterioration or amelioration, respectively, at an interglacial–glacial stage boundary (Fedoroff and Goldberg, 1982; Fedoroff et al., 1990). Fragmented clay coatings (Figure 6(f)) within polygenetic or ‘paleoargillic’ buried and nonburied paleosols in temperate latitudes, particularly when associated with identifiable cryogenic features, are traditionally interpreted in terms of a period of clay illuviation during an interglacial followed by freeze–thaw disruption during a cold stage (Avery, 1985). Undisturbed clay coatings in clear microstratigraphic association with fragmented clay coatings (Figure 6(g)) have been used to imply subsequent reversion to interglacial conditions (Kemp and Faulkner, 1998). However, considerable care must be taken in assigning too strict a climatic significance to such microstratigraphies, bearing in mind uncertainties regarding the environmental factors controlling particle translocation and the possibility of other disruptive processes being responsible for fragmentation. Furthermore, when dealing with polygenetic paleosols potentially spanning several interglacial–glacial cycles, there are undoubtedly situations in which the pattern of micromorphological features is so variable and complex that it is impossible to unravel and provide a coherent and reliable reconstruction (Kemp and Faulkner, 1998).

Micromorphological Reconstructions of Pedosedimentary and Landscape Evolution

The realization of the need to take into account the changing forms and balances of pedogenic and sedimentary inputs over time in the interpretation of many pedocomplexes and alluvial, colluvial, or eolian sequences containing paleosols has led to a move away from traditional approaches that tend to encourage the examination of paleosol units as discrete static entities formed at single stable land surfaces (Kemp, 1998). From a micromorphological standpoint, this pedosedimentary approach requires consideration of depth trends in type and abundance of micromorphological features throughout the stratigraphic column, not just within field-designated paleosol horizons. Quantification of the key pedological and sedimentary features in each thin section allows the construction of micromorphological depth functions and the identification of levels or zones marking changes in balances and/or types of inferred pedogenic and sedimentary processes. Interpretation of these depth functions and any associated microstratigraphic relations of key features, independently or along with existing field and bulk analytical data, provides the basis for the reconstruction of the landscape evolution in terms of a series of pedosedimentary stages (Kemp, 1999).

Following this approach, relatively simple microstratigraphic associations such as secondary carbonate postdating clay within compound coatings (Figure 6(c)) may be interpreted to reflect overprinting of a paleosol through leaching and redistribution of calcite from soils higher up in the stratigraphic sequence. Other micromorphologically based reconstructions of welded paleosols may involve more complex sequences of sedimentation, erosion, and pedogenic phases (Figure 7). In some

Figure 7 Key micromorphological fabrics in a thin section from a buried welded paleosol at Attenfeld (Germany) and the schematic reconstruction of its pedosedimentary development. Stage 1: deposition of solifluction sediments, soil development with accumulation of clay coatings in lower horizons (thin section D), followed by cryogenic disturbance with fragmentation of clay coatings toward the top of the soil (thin section C). Stage 2: truncation, deposition of a thin unit of solifluction sediments, soil development with accumulation of clay coatings in both the new deposits and those lower down where superimposed on the existing cryogenic fabric (thin section C), followed by cryogenic disturbance with fragmentation of clay coatings and formation of cryoturbated granular aggregates toward the top of the soil (thin section B). Stage 3: truncation, deposition of a thick unit of calcareous loess, and soil development extending through loess but not into underlying welded paleosol (as evidenced by preservation and lack of dissolution of shells in the lower part of calcareous loess; thin section A). Reprinted from Kemp RA (1999) *Micromorphology of loess–paleosol sequences: A record of paleoenvironmental change Catena* 35: 179–196. © 1999, with permission from Elsevier.

Figure 8 Depth function of the main micromorphological features and the associated reconstruction of pedosedimentary stages responsible for the development of part of a loess sequence at Gaolanshan in western China. A paleosol had been identified between 32.2 and 33.5 m on the basis of peak values of magnetic susceptibility, but pedogenic activity of environmental significance is clearly revealed in the thin sections within the loess above. Stage 1: deposition of loess, establishment of a relatively stable land surface, and development of a bioturbated weak leaching profile (zone of excrements and partially dissolved calcite overlying concentrations of secondary carbonate in the form of calcitic segregations and hypocoatings) equivalent to the lower part of the paleosol unit identified on the basis of magnetic susceptibility. Stage 2: deposition of loess with sufficient moisture available for localized redistribution of calcium carbonate as the surface accreted (compound calcitic concentration-depletion features, partially dissolved calcite and coincidental calcitic segregations and hypocoatings). Stage 3: deposition of loess under generally drier conditions (no calcitic features), with ephemeral sparsely vegetated surfaces subjected to infrequent intense rain (crusts) and with freeze-thaw processes (banded fabric) active at times. Reprinted from Kemp RA (1999) Micromorphology of loess-paleosol sequences: A record of paleoenvironmental change. *Catena* 35: 179–196. © 1999, with permission from Elsevier.

colluvial, alluvial, or loess environments, pedogenesis and sediment deposition effectively take place continuously and simultaneously within a geological time framework. Micromorphology can be very useful in identifying relict biofabrics of A horizons that have been transformed to B horizons as sediments have accreted (Figure 6(h)) and also recognizing pedogenic activity of environmental significance within field-designated sedimentary units (Figure 8). Indeed, in situations in which sedimentation rates are rapid, the pedosedimentary sequence

may be so detailed as to provide a semicontinuous record of fine-scale paleoenvironmental changes (Figure 9).

Figure 9 Pedosedimentary log based on the vertical changes in relative influences of different post- and syndepositional processes inferred from thin sections spaced at close vertical intervals through the rapidly accreting loess (L)–paleosol (S) sequence at Jiouzhoutai in western China. Each pedosedimentary unit may be interpreted to reflect specific environmental conditions (e.g., unit 14 is dominated by cryogenic features and secondary gypsum formed as loess was accumulating under a cold dry environment; unit 9 represents slightly moister conditions, supporting syndepositional bioturbation and localized redistribution of calcite; and unit 3 marks a reduction in loess accretion and establishment of a relatively stable land surface under a warmer and moister environment, supporting mollusk habitation, significant bioturbation, and vertical leaching and redistribution of carbonate). Thus, the high-resolution pedosedimentary sequence provides a relatively detailed semicontinuous record of paleoenvironmental change. Weathering Profiles

Introduction

Weathering is a process of conversion of rock-forming minerals toward an equilibrium state. Rocks and sediments at or near the Earth's surface are subjected to physical, chemical, and biological environments that differ from those present where constituent minerals formed, and by various processes they change toward equilibrium with Earth-surface conditions (Taylor and Eggleton, 2001). Weathering processes are grouped into two broad categories: mechanical (physical) weathering and chemical weathering. The former involves changes that do not directly result in chemical or mineralogical changes to the affected geological materials, whereas the latter result in a variety of mineralogical and chemical changes to the original materials. Mechanical and chemical weathering can and often do occur together, and both can be mediated by biota. These changes to rocks and sediments are organized into weathering profiles that reflect the interplay of weathering, erosion, and redistribution of material at and below the land surface over time. Alterations of geologic materials that take place in weathering profiles produce physical, chemical, and hydrologic characteristics that influence urban and agricultural land use, water resources, the occurrence of some economically important deposits, and landscape evolution. Weathering profiles range from centimeters to tens of meters in thickness. They begin developing upon exposure at the land surface and may form over tens of millions of years in some stable continental interiors. Fossil-weathering profiles occur throughout the geologic record, becoming more common with the spread of land plants in the Carboniferous. Because weathering profiles form from the land surface, some of their properties may reflect climatic conditions during their formation and thus provide information useful for paleoenvironmental reconstructions. Weathering profiles are the 'roots' of surface soils and reflect the cumulative effects of near-surface alterations of geologic materials over extended periods of time.

The literature on weathering profiles is replete with terms for weathered geologic material. The most all-encompassing term is regolith – the mantle of fragmented and usually un lithified geologic material that overlies bedrock and that includes residual and transported materials. Some definitions include soil as the upper zone of the regolith, whereas engineering geologists often call all unconsolidated material above bedrock 'soil.' The regolith consists of several distinct materials that may be intimately related (Ollier and Pain, 1996):

1. *Weathered rock*. Weathered rock in place is saprolite, a soft, earthy, typically clay-rich, thoroughly decomposed rock formed in place by chemical weathering of igneous, metamorphic, or sedimentary rocks (Figure 1). Structures present in the original rock, such as veins and fractures, are preserved in saprolite.

2. *Residuum*. Material originally formed by weathering of rock that has subsequently moved a short distance, either by creep or through removal of finer weathering products.
3. *Transported sediments and chemical deposits*. Materials transported by various agencies from a place of origin, where they were weathered to become available for transport, to a place where they have been deposited.
4. *Soil*. Physical, chemical, and biological alterations of geologic materials that occur immediately below a land surface and that grade downward into a weathering profile.

Weathering profiles are formed in regolith. They may be defined as the vertical extent of a weathered sequence from the initiating land surface or the originating surface to the unweathered parent rock. Weathering profiles form by chemical and mechanical weathering and vary considerably on several spatial scales because of variations in materials they are formed in, topography, hydrology, surficial processes, and climate.

Weathering Processes

Both mechanical and chemical weathering processes act to form weathering profiles. The boundary between the weathered and unweathered material in a weathering profile is called the weathering front (Mabbutt, 1961). The weathering front marks important differences in permeability, porosity, strength, and behavior, and it is the locus of initial changes in the unweathered geologic material that begin the weathering process. Advance of the weathering front occurs along and is dependent on the presence of fractures that allow the penetration of meteoric fluids into the unweathered material (Figure 2). Thus, rock types, tectonic and climatic settings, and landscape conditions that favor the formation of extensive interconnected fracture networks facilitate the development of weathering profiles (Figure 3). Some of the more important mechanical weathering processes include expansion from release of confining pressure (unloading), exfoliation, frost shattering, pressure induced by root growth, and pressure resulting from the growth of salt crystals. Water enters unweathered material on the macroscale by penetration along interconnected pores, primarily fractures in rocks, lithified sediments, and unlithified fine-grained sediments. Also of great importance is the presence of intra- and transgranular microcracks formed by a variety of forces, including crystallization, tectonics, and unloading. The microcrack systems are the loci of water-mineral interactions that are the initial stages of chemical weathering (Bisdom, 1967).

The effects of rock or sediment texture on penetration of the weathering front are fundamental (Thomas, 1974). Disaggregation of coarse-grained rocks such as granite into constituent

Figure 1 Clay-rich saprolite formed by in-place chemical weathering of biotite granite–gneiss. Protolith texture and structures are preserved in core stones such as the one in the lower part of this profile. Photograph by M.J. Pavich.

Figure 2 Oxidation, marked by brown and reddish brown colors, advances into gray, unweathered middle Pleistocene glacial diamicton along subvertical fractures. The fractures are avenues along which meteoric water and the solutes it carries penetrate the deposit, thereby advancing the weathering front. Photograph by E.A. Bettis.

Figure 3 Flowchart showing the primary factors acting to advance the weathering front in geologic materials.

mineral grains by oxidation of biotite and hydration of other minerals often takes place before much fundamental chemical change has occurred. Fine-grained rocks of similar mineral composition weather more slowly, most likely because a system of microcracks and larger, interconnected fractures is usually not as extensively developed in these rocks. In arid, polar, and some coastal environments, crystallization from supersaturated solutions of adventitious salts (salts derived from sea spray or saline water bodies) can produce expansive stresses

leading to granular disintegration or scaling. The various physical and chemical processes acting at the weathering front act to make this a zone of relatively high hydraulic conductivity in a weathering profile. This promotes downward progression of the weathering front by transporting weathering products away from the loci of weathering (Figure 3).

In the early stages of weathering, hydration (the addition of water to a mineral) produces an increase in volume. As weathering progresses, this gives way to a volume loss as solutes are transported away from the locus of weathering by soil water and/or groundwater movement (leaching). Other chemical weathering processes, including oxidation, reduction, hydrolysis, carbonation, and chelation, act to bring about significant changes to weathering materials. In weathering, oxidation simply means a reaction of materials with oxygen to form oxides or, if water is incorporated, hydroxides. The oxygen can be derived directly from the atmosphere, from oxygen dissolved in water, or from bacterial activity. Reduction is the opposite of oxidation and usually takes place in anaerobic (oxygen-deficient), water-logged sites. Carbonation is the reaction of carbonate and bicarbonate ions with minerals. Carbonate and bicarbonate ions are common intermediate products in certain types of weathering, particularly the breakdown of feldspars. In one of the most common carbonation reactions, carbon dioxide (CO_2) reacts with water to form carbonic acid (H_2CO_3), a potent solvent in weathering environments. In the process of chelation, an ion, usually a metal, is held within an organic ring structure. Chelating agents allow the removal of ions from otherwise insoluble solids and enable the movement and precipitation of metallic ions in weathering profiles. Hydrolysis is a very effective chemical weathering process in which ions of minerals and the H^+ or OH^- ions of water react. The concentration of hydrogen ions is of fundamental importance in all weathering reactions (Ollier and Pain, 1996). In weathering profiles, the roots of living plants and acid hydrogen clay (clay with a high proportion of H^+ ions on its cation exchange sites) are primary sources of H^+ ions, which create an acid environment that promotes mineral weathering.

As a consequence of increasing efficacy of mechanical and chemical weathering toward the land surface, most weathering profiles exhibit trends of decreasing particle size, increasing clay content, and increasing voids ratio toward the surface (Gerrard, 1988). Chemical weathering of common rock-forming minerals produces only a few abundant groups of secondary minerals. Because the secondary minerals produced during weathering develop preferentially after specific primary minerals, the secondary mineralogy of most weathering profiles is dependent on the primary mineralogy and its distribution in the source rock (Nesbitt and Young, 1989). The application of weathering indices to weathering profile evaluation emphasizes a continuum of change from fresh to highly altered materials and provides numerical expression to the chemical or mineralogical changes imparted by weathering. The basis of chemical weathering indices is that some elements (e.g., Ca, Na, and K) found in weatherable minerals (e.g., feldspars, pyroxenes, amphiboles, and micas) are relatively mobile, whereas others (e.g., Al, Fe, and Ti) are not. As weathering progresses, the proportion of mobile elements remaining in the weathering materials decreases while the proportion of immobile elements increases. The chemical index of alteration

(CIA) developed by Nesbitt and Young (1982, 1989) is based on the molecular proportions of major element oxides:

$$\text{CIA} = [\text{Al}_2\text{O}_3 / (\text{Al}_2\text{O}_3 + \text{CaO} + \text{Na}_2\text{O} + \text{K}_2\text{O})] \times 100$$

The CaO in the equation is attributable only to silicates, necessitating the subtraction of nonsilicate CaO in materials in which they occur in significant quantities. Values of CIA increase from 50 to 55 for primary minerals, such as biotite and feldspar, to 100 for secondary minerals, such as kaolinite and gibbsite, with intermediate values (70–85) for smectites. Sueoka (1988) proposed the chemical weathering index (CWI), also based on molecular weight proportions in which

$$\text{CWI} = [\text{Al}_2\text{O}_3 + \text{Fe}_2\text{O}_3 + \text{TiO}_2 + \text{H}_2\text{O}(\pm) / \text{all chemical components}] \times 100\%$$

Several studies have shown progressive increase in both CWI and CIA toward the land surface in weathering profiles developed on granitic rocks. The character of weathering products within a weathering profile and among weathering profiles depends on the weathering environment because the mobility of the cations released during weathering of silicate rocks varies widely and is affected by the pH and, in the case of iron, the electron potential (E_h) of groundwater (Thomas, 1974). The most mobile elements are usually lost to the site of weathering in solution; elements with intermediate mobility remain in solution for short periods and often are precipitated as new minerals close to the site of weathering. Aluminum and iron in the ferric state, the least mobile of the common elements, generally remain as residual products of weathering, usually as sesquioxides.

Water is a prerequisite to chemical weathering because it provides and carries away reactants, thus playing a significant role in the direction and progression of weathering (Figure 3). In general, weathering progresses to deeper levels and at faster rates where groundwater gradients are steepest. Organic matter and biological processes also play critical roles in the development of weathering profiles. Plants and burrowing animals mix and cycle materials through weathering profiles. Organic acids produced during organic matter degradation form organic acids that lower pH, and they also form complexes (chelates) with metal cations that increase the solubility of important elements bringing some elements such as iron into solution in weathering profiles. Microbes, primarily bacteria, also reduce iron(III) and Mn(III) and Mn(IV) in saturated to near-saturated parts of weathering profiles to reduced ions that move through or out of the weathering profile in solution.

Oxidation, another important process in weathering profiles, occurs when geologic materials exist in an environment in which the oxygen supply is high or exceeds the biogeochemical oxygen demand (BOD). Most oxidation in weathering profiles occurs when oxygenated waters come in contact with mineral grains. Iron is the most commonly oxidized element. The oxidation of iron, from the ferrous (Fe(II)) to the ferric (Fe(III)) state, disrupts the electrical neutrality of the crystal lattice, promoting the formation of an oxide, hematite (Fe_2O_3), or a hydrous oxide such as goethite. These iron minerals impart brown, red, or yellow color to the weathered material (Figure 4).

Reduction (sometimes referred to as 'deoxidation') occurs in an environment in which the oxygen supply is limited or the

Figure 4 Yellowish brown colors in the upper, oxidized part of this exposure of loess give way to gray matrix colors and reddish brown mottles in the lower reduced (deoxidized) part of the exposure. Iron ions in the matrix of the oxidized zone are dominantly ferrous (Fe(II)), whereas in the reduced zone the matrix contains abundant ferric iron (Fe(III)). Iron oxides and hydrous oxides are abundant in the mottles where ferric iron, mobilized from the reduced matrix, moved to pores where higher Eh promoted the formation of iron oxides. Photograph by E.A. Bettis.

BOD is high. Saturation or near saturation and the presence of organic matter and microbes are prerequisites for this process. In this environment, iron is reduced to its mobile ferrous form. Once in this form, iron may be lost through net movement of the groundwater; it may remain in the sediment matrix and react with sulfides; or it may move into fractures, pores, or other voids and be oxidized. Matrix colors in a reduced zone usually range from gray to greenish gray, a condition reflecting relatively low free iron oxide content (Figure 4). In contrast to the grayish matrix, fractures and pores in reduced zones, where iron has migrated and become oxidized, have brown and reddish brown stains, streaks, and mottles.

If geologic material has not been exposed to atmospheric oxygen or oxygenated water, it may be unoxidized. In this state, most iron is in the ferrous form, and the matrix is a uniform dark gray color without stains, streaks, and mottles (Figure 5).

Weathering processes lead to the development of a weathering profile if the rate of weathering exceeds the rate of removal of weathered material by surface erosion. The upper part of the weathering profile is dominated by processes that remove soluble weathering products in solution and that lead to the concentration of more inert minerals and secondary products, such as iron oxides, that accumulate as residues. The soil profile is located at the top of this part of the weathering profile. The materials lost in solution may be removed entirely by groundwater flow or reprecipitated, either lower in the weathering profile or downslope elsewhere on the landscape.

Figure 5 Unoxidized glacial diamicton with uniform dark gray matrix color and lack of brown or red mottles, streaks, and stains. Unoxidized materials have not been exposed to the atmosphere or to oxygenated water for a period of time sufficient for oxidation of their matrix iron to begin. Photograph by T.J. Kemmis.

Weathering Zones

Weathering profiles can be subdivided into zones on the basis of physical, chemical, and mineralogical properties of the regolith. The simplest subdivision of the weathering profile includes two zones: an upper mobile or 'active' zone, which has been affected by biological and abiotic disturbance of weathered material, and a lower zone of *in situ* weathered material recognized by little or no volume change from the unweathered geologic material, the presence of joint planes, veins of resistant minerals, or other rock structures. The lower zone is usually referred to as 'saprolite.'

Walther (1916) is credited as the first to formalize the sequence of zones found from the surface downward in deep-weathering profiles:

1. soil and duricrust,
2. mottled zone,
3. pallid zone, and
4. fresh bedrock.

This sequence has subsequently come to be called a 'laterite' profile. The pallid zone has preserved rock structure, is depleted in metallic cations, and usually contains kaolinite. The mottled zone contains patches of iron oxide in a pallid zone matrix and may extend up into the active zone. Several variations on Walther's original scheme have been presented, and the reader is referred to Gerrard (1988) and Ollier and Pain (1996) for examples. Ruxton and Berry (1957) developed a physical and chemomineralogical classification scheme for weathering zones developed in granite:

1. residual debris composed of structureless sandy clay or clayey sand, 1–25 m thick with up to 30% clay, composed

- predominantly of quartz and kaolin, reddish brown when clayey and light brown or orange when less clayey;
2. residual debris with less than 10% free, rounded corestones (spheroidal boulders of fresh rock), less than 5% clay but common clay-forming minerals, generally light color;
 3. similar to (2) but with much of the original rock structure preserved and 10–50% corestones;
 4. rectangular and locked corestones (50–90% solid rock) set in a matrix of residual debris; and
 5. partially weathered rock with minor amounts of residual debris along major fracture planes, more than 90% solid rock, significant iron staining and biotite decomposition may be present.

Figure 6 illustrates some of the more commonly used classification schemes for weathering profiles in crystalline rocks.

The specific features of weathering profiles and the zones they comprise vary, depending on the physical and chemical nature of the materials in which they form, as well as across landscapes. The weathering zone schemes of [Walther \(1916\)](#) and [Ruxton and Berry \(1957\)](#) are characteristic of those formed in crystalline rocks. Weathering profiles in sedimentary rocks seldom exhibit the distinct zoning, corestones, and well-defined basal surface of weathering associated with crystalline rocks. Relatively pure carbonates such as chalks typically have very thin weathering profiles. The residuum of carbonate rock weathering profiles contains large amounts of insoluble rock

constituents, such as quartz, chert, iron, and manganese oxides and clay minerals. Large fractures, bedding planes, and solutional openings in carbonates foster extreme lateral variability of these weathering profiles (**Figure 7**). Weathering profiles formed in siltstones and mudstones are characterized by a

Figure 7 Weathering profile formed in limestone. Note variations in the weathering profile associated with the occurrence of fractures and bedding planes in the rock. Also note the presence of residual chert clasts in the upper part of the profile. Photograph by E.A. Bettis.

Figure 6 Six weathering zone classifications in common use for weathering profiles formed in crystalline rock. Modified from Taylor RG and Howard KWF (1999) Lithological evidence for the evolution of weathered mantles in Uganda by tectonically controlled cycles of deep weathering and stripping. *Catena* 35: 65–94; Figure 4.

*All possible weathering zones or weathering zone combinations not indicated

Figure 8 Weathering zone schemes commonly applied to unlithified deposits in the United States.

relatively thin low-strength and low-permeability zone near the surface that grades downward into a jointed and fissured zone of higher permeability (Deere and Patton, 1971). Fissures are extremely important features in the weathering of shale, siltstone, and mudstone. They often develop along bedding planes, from structural modifications, and as a response to unloading and land surface processes.

Weathering profiles in unlithified sediments have generally received less attention than those formed in rock. Glacial sediments, loess, eolian sand, alluvium, and exposed marine sediments are widespread in many areas of the world. Weathering zones in these materials are typically identified by color changes, mottling patterns, the presence/absence of fractures, and sometimes chemical changes such as carbonate leaching or accumulation. Three weathering zone schemes for unlithified sediments are in general use (Figure 8):

1. Birkeland (1999) used the designation 'Cu' for unoxidized material and 'Cox' for oxidized material.
2. Hallberg et al. (1978) used a more elaborate scheme that can be applied to materials whose unaltered state is oxidized or unoxidized (Table 1).
3. Tandarich et al. (1994) provided a classification that unifies unaltered deposits and the overlying soil profile into a single 'pedo-weathering profile.'

A conceptual problem common to all these classification schemes is that they imply a genesis beyond their simple description – an unfortunate circumstance given the great uncertainty surrounding the mechanisms by which weathering mantles develop. Taylor and Howard (1999) proposed the use of strictly descriptive graphic logs, similar to those employed to describe lithostratigraphy, as a way to objectively describe weathering profiles. Practical problems with applying weathering zone schemes to unlithified sediments usually center around two issues: (1) determination of the physical and chemical properties of the initial material that has undergone weathering and (2) complications with using color as a proxy for oxidation state in materials that contain significant amounts of detrital carbon.

Spatial Patterns of Weathering Profiles

Much discussion has focused on the distribution of thick weathering profiles, their age, and conditions fostering their development. Common assumptions are that deep weathering is associated with warm, wet climates and that the development of thick weathering profiles implies great age of the associated geomorphic surface. Although greater amounts of

Table 1 Weathering zone terminology proposed by Hallberg et al. (1978) for Quaternary materials

<i>First symbol</i>	<i>Munsell color reference</i>
O (oxidized)	60% of matrix with hues redder than 2.5Y; hues of 2.5Y with values of 5 or higher; may have segregation of secondary Fe and Mn compounds into mottles, nodules, etc.
R (reduced)	60% of matrix with hues of 2.5Y with values of 3 or less; hues of 2.5Y with value of 4 and chroma of 2 or less; hues of 5Y, N, 5GY, 5G, 5BG, 10Y, and 10GY with values of 4 or higher; colors are usually mixed as mottles, bands, or diffuse blends of colors; may have considerable segregation of secondary Fe and Mn compounds into mottles, nodules, etc.
D (deoxidized – applied only to loess)	60% of matrix with hues of 10YR, 2.5Y, and/or 5Y, values of 5 and 6, and chromas of 1 or 2; segregation of Fe compounds into tubules and/or nodules
U (unoxidized)	Uniform matrix color; hues of 5Y and N with values of 5 or less; 5GY, 5G, 5BG, 10Y, and 10GY with values of 6 or less; no secondary segregation of Fe and Mn compounds
<i>Second symbol</i>	<i>Fractures (if present)</i>
J (jointed – fractured)	Well-defined vertical to subvertical fractures present; often identified by colors that contrast with the matrix and coatings and/or rinds of secondary minerals
<i>Second or third symbol</i>	<i>Leached or unleached state – used only with materials having primary matrix carbonate</i>
U (unleached)	Reacts with dilute HCl
L (leached)	Does not react with dilute HCl
L2	Leached of primary carbonates but secondary carbonates present as coatings, nodules, or other accumulations
<i>Modifier symbol</i>	<i>When used precedes first symbol</i>
M (mottled)	Has zones with 20–50% contrasting mottles; when used with the unoxidized zone it infers 20% or less mottles of reduced colors
<i>Examples of descriptions using weathering zone terminology</i>	
OL	Oxidized and leached; yellowish brown (10YR5/6) matrix color, does not react with weak HCl
MOU	Mottled, oxidized, and unleached; strong brown (7.5YR4/4) matrix color with common gray (5Y5/1) and light olive brown (2.5Y5/4) mottles, reacts with weak HCl
UJU	Unoxidized, jointed, and unleached; uniform dark greenish gray (5GY4/1) matrix with few thin vertical fractures which have mottled light olive brown (2.5Y5/6) and olive gray (5Y5/2) faces, reacts with weak HCl

water passing through a material and higher temperatures will speed chemical weathering, the depth of weathering is a function of the rate of weathering profile advance and the rate of erosion. Thus, weathering profile thickness is related to rock/sediment properties, environmental history, and geomorphic history. Since the effects of rock and sediment properties have already been discussed, this section focuses on the role of

environmental and geomorphic history on weathering profiles. Strakhov (1967) proposed five global-scale zones of weathering related to latitudinal variations in climate and vegetation (Figure 9). He also recognized three major disturbances to the latitudinal pattern: glacial sedimentation, arid sedimentation, and active tectonics. Weathering profiles on intrusive igneous rocks, such as granite, have been described and studied in many areas of the world and have provided a 'standard' for comparing global patterns. The development of thick weathering profiles has traditionally been associated with humid tropical and subtropical environments, and their occurrence in areas with other climatic regimes has been cited as evidence of relict weathering under past wetter and/or warmer climates.

With several caveats, the assemblage of clay minerals formed in weathering profiles in granitic rocks generally reflects the climatic regime or annual rainfall average of the area (Gerrard, 1994). In arid regions, where leaching is not intense, smectite is the dominant alteration product. Illite (mica) is probably a poor indicator of macroclimatic conditions because it rarely forms in weathering environments. Kaolinite can be produced under a variety of climatic conditions. It can dominate very wet temperate regions, and it is the most commonly reported secondary clay mineral in wet tropical environments. In addition to kaolinite, smectite can occur in drier tropical regions, and gibbsite and boehmite can occur in the wettest regions. Seasonality of precipitation is also important, and weathering profiles in areas with monsoons often contain illite and montmorillonite.

Other characteristics of weathering profiles, such as particle-size distribution, have also been suggested as indicators of climate-driven weathering. Two end member types of profiles formed on granitic rocks, 'arenaceous' or sandy profiles and 'argillaceous' or clayey, have been defined. Sandy regoliths are widely distributed in temperate regions, contain common to abundant weatherable minerals, and form primarily by the alteration of plagioclase feldspars to clay, accompanied by mechanical fracture of quartz and orthoclase to sand-size material. In contrast, argillaceous regoliths, most commonly found in wet tropical and subtropical regions, contain few weatherable minerals and have high clay and low silt content due to the rapid transformation of all feldspars directly to clay minerals.

Weathering profile characteristics also vary across landscapes. Although the primary control on weathering profile thickness appears to be the intensity and direction of jointing in rocks, landscape-related patterns are also apparent. Thomas (1974) summarized evidence relating deep-weathering profiles to topography:

- The weathering front is usually highly irregular and usually exhibits a pattern of discrete basins and domes.
- Weathering patterns are aligned with the fracture system developed in the rock.
- Weathering depth is usually shallow beneath streams.
- Where marked inequalities in the resistance of rock do not occur, the depth of weathering usually increases irregularly away from streams toward interfluvies in the humid tropics.
- In drier savannas and semiarid regions, deep-weathering profiles are usually restricted to depressions in the landscape.

Figure 9 Pole-to-equator variation of weathering profiles as proposed by Strakhov (1967). Adapted from Figure 9.10 in Schaetzl RJ and Anderson S (2005) *Soils: Genesis and Geomorphology*. New York: Cambridge.

Figure 10 Weathering profile developed beneath a slope formed in late Pleistocene glacial diamicton. The oxidized zone is thick beneath the summit, thins beneath the sideslope, then thickens in the lower part of the slope where sandy zones promote deep penetration of oxygenated water. Weathering zone terminology of Hallberg et al. (1978): OL, oxidized and leached; JOU, jointed oxidized and unleached; UU, unoxidized and unleached; MJOU, mottled jointed oxidized and unleached. Photograph by T.J. Kemmis.

- High relief and steep slopes foster a pattern of rocky hills and weathered valley floors in both humid and arid areas.
- Patterns of surface relief may offer few clues to deep-weathering patterns.

Weathering profiles formed in Quaternary sediments that have been dated provide insights into spatial patterns of weathering profiles during the early stages of their development (Figure 10). General trends include:

- advance of the weathering front along fractures and other pores in the sediment matrix;
- increasing thickness of weathering profiles with increasing coarseness of the sediment matrix;
- deeper penetration of the weathering front on uplands near valley margins than beneath either uplands distant from

valleys or beneath valley floors except in arid and semiarid regions, where the thickest weathering profiles are found in valleys;

- weathering profiles that are thicker in well-drained than in poorly drained landscape positions, again with the exception of arid and semiarid regions;
- increasing thickness of weathering profiles in well-drained landscape positions with increasing mean annual infiltration;
- correspondence between oxidation state of dominant ferromanganese oxides (and therefore sediment matrix color) and the position of the water table;
- great complexity in the details related primarily to variations in sediment properties (bedding, structure, porosity, density, and mineralogy), water movement through the sediment, biotic effects, and the nature of surface erosion.

Dating Weathering Profiles

There are many problems surrounding generalizations about the relationship among weathering profile thickness and morphology and the age and stability of geomorphic surfaces; however, as Thomas (1974) suggested, deep lateritic profiles with thick pallid zones, as well as distinctly zoned weathering profiles, are probably reasonable indicators of surface stability and prolonged development. Deep-weathering profiles are not the product of a single weathering event in a well-defined time in the past but are the combined result of long-lasting superimposed weathering processes during extended periods of time. Changes in climate, vegetation, and landscapes over the length of time during which weathering has taken place complicate the interpretation of weathering profile histories. Most deep-weathering profiles occur in relatively stable cratonic regions that were not directly affected by glaciation during the Quaternary, or are in stratigraphic positions indicating development prior to the Quaternary.

Three methods have been used to determine the age of deep-weathering profiles: K–Ar, $^{40}\text{Ar}/^{39}\text{Ar}$, and cosmogenic isotope dating. The age of neoformed alunite-group sulfates (alunite and jarosite) and hollandite-group manganese oxides (cryptomellane and hollandite) precipitated through weathering reactions can be determined using K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology (Vasconcelos, 1999). Supergene alunite and jarosite, because of the relative simplicity of their mineral structures, can be dated equally well using either method, provided that large enough quantities of pure mineral separates can be obtained. On the other hand, the complex nature of supergene Mn oxides and the large number of mineral structures encompassed by the Mn-oxide group make application of the $^{40}\text{Ar}/^{39}\text{Ar}$ incremental-heating methodology better suited to dating these phases (Vasconcelos, 1999). The K–Ar and $^{40}\text{Ar}/^{39}\text{Ar}$ methods can be applied across the full sweep of geologic time, but age measurements at the young end of the spectrum are more likely to be compromised by contamination with atmospheric Ar or primordial ^{40}Ar . The $^{40}\text{Ar}/^{39}\text{Ar}$ method allows for assessment of such contamination and therefore performs better in the younger (0.25–1.0 Ma) age range.

Cosmogenic ^{10}Be inventories have been used to estimate the length of accumulation time and hence the minimum age of weathering profiles formed during the past 5 Myr (Pavich et al., 1985). Complexities such as surface erosion and shielding effects of glacial ice limit the application of this technique in some areas, but several studies have successfully applied this and other cosmogenic isotope dating techniques to Quaternary weathering profiles (Pavich, 1986; Phillips et al., 1998).

Applications

Knowledge of the distribution, properties, origin, and age of weathering profiles has a wide variety of geological, engineering, hydrological, and land-use applications. Initially, interest in weathering profiles was fueled by geologists seeking to understand the origin and distribution of economically important supergene minerals and ores associated with some deep-weathering profiles. Subsequently, geologists also began to realize that information on the nature and distribution of past climates could also be gleaned from weathering profiles. In many cases, truncated weathering profiles are the only surviving evidence of ancient geomorphic surfaces (Bettis, 1998; Figure 11). Geochemical, isotopic, and geochronological studies of weathering profiles provide important insights into long-term erosion rates and landscape evolution. Engineers and engineering geologists have long appreciated the variations in physical properties of the regolith that occur through weathering profiles. Mapping the thickness and properties of weathering profiles has added a new dimension to land-use planning, construction engineering, and landslide hazard assessment (Hencher and McNicholl, 1995). Infiltrating water moves through weathering profiles on its way to both discharge areas and aquifers. Variations in hydrologic and hydrochemical properties of weathering profiles control many important aspects of water movement and quality in the vadose (unsaturated) and shallow phreatic (water-saturated) zones that have critical impacts on water supplies in many areas of the world.

Figure 11 (a) A weathering profile formed in late Pleistocene glacial diamicton overlying another weathering profile formed in older glacial diamicton. The contact between the gray unoxidized and unleached (UU) diamicton and the underlying brown oxidized and leached (OL) diamicton marks a significant stratigraphic break during which the lower weathering profile developed. Photograph by T.J. Kemmis. (b) Abrupt contact between unoxidized and unleached and oxidized and leached glacial diamictons. The presence of an unoxidized zone overlying an oxidized zone marks a significant stratigraphic break. Upper parts of the oxidized unit's weathering profile were removed by glacial erosion during advance of the glacier that deposited the upper diamicton. Photograph by E.A. Bettis.

Conclusions

Weathering profiles form over extended periods of time as geologic materials are altered in response to physical and chemical changes in the near-surface environment. Weathering profiles are the long-lasting 'roots' of surface soils, and their properties reflect the cumulative effects of weathering under changing climatic, biotic, and geomorphic conditions at a given location. Variations in the factors that affect weathering from place to place on a landscape, around the globe, and through time, have produced patterns in the properties of weathering profiles. Deciphering the history preserved in these patterns can provide information crucial to understanding long-term processes that shape the Earth's surface and that affect the environment in which we live.

Introduction

One of the most fundamental characteristics of all soils that enable their recognition is that they exhibit 'horizon' development as the most fundamental aspect of a soil profile (i.e., A–B–C profiles of 'master horizons'; [Figure 1](#)). This aspect of soils also allows them to be distinguished from other Earth materials that have some features that strongly resemble those of soil. Soil horizons are recognized on the basis of key attributes that distinguish them from the materials in which they are formed, called soil 'parent materials.' Chemical, mineralogical, and biological aspects of soils are used to define different soil horizons, but soil morphologic features are the main basis for recognizing and describing them in field settings.

Soil scientists formally recognize literally dozens of soil morphological properties ([Buol et al., 1997](#)). Some of the more important properties include soil texture, structure, color, mottling, surface coatings, and horizon thickness. These properties can be used to identify the master horizons because certain key properties strongly characterize them. For example, the A horizon typically is brown to dark brown, reflecting the accumulation of humus (organic matter in various states of chemical decomposition), one of the hallmarks of nearly all A horizons. In contrast, the E horizon is generally pale, largely reflecting the loss of iron minerals through certain chemical weathering reactions. Characterization of these and other properties (signified by the use of small case letters associated with specific pedogenic features) is used to identify soil 'genetic' horizons and 'subhorizons' (e.g., Bs horizon; 's' signifies presence of iron and aluminum oxides that formed in the soil). When combined with other types of data (e.g., textural, chemical, mineralogical, and micromorphological), 'diagnostic' horizons (e.g., argillic horizon) are designated ([Figure 2](#)). Such horizons are the primary basis for the classification of soils in the United States Department of Agronomy Soil Taxonomy.

The Relation of Soil Properties and Soil-Forming Processes

The emergence of soil properties is the result of a large number of soil-forming 'processes.' For example, soil texture, a morphological property defined as the relative proportions of sand, silt, and clay in the 'fine earth' (i.e., particles less than 2 mm in diameter), changes because of certain processes. One is the movement of rainwater through a soil, which causes a change in soil texture of the fine fraction of the soil parent material by the following:

1. Causing 'translocation' of fine soil particles from shallower to deeper parts of the soil. Different kinds of translocation include transport of mass as colloids, solid particles, and solutes. So, changes in soil texture that largely reflect

increases in clay content (a key morphological feature of argillic horizons in important soil orders like Aridisols, Alfisols, and Ultisols) are related to processes of translocation.

2. Chemical weathering, which can cause the formation of clay by alteration of soil parent material minerals (e.g., feldspar).
3. Physical weathering (also known as mechanical weathering), which is the physical breakdown of large particles into smaller particles.

Dissolved salts in soil water may move into larger parent material grains, causing them to disintegrate by process of salt weathering. These examples show that the formation of many soil morphological properties is often complicated, because essentially all soil properties are the expression of the influences of a very large number of different soil-forming processes that may operate at varying times (daily or seasonal) and magnitudes. These processes may also affect the character of A or C horizons, but they mainly operate in and help produce many of the important features that are fundamental to 'B' horizons.

Another important morphological property is soil color. It is often one of the most obvious and easily recognized soil morphological properties. Studies of soils in many landscapes show that they exhibit great variation in color, both among soils of different types ([Figure 3\(a\)–3\(c\)](#)) or between different horizons ([Figure 3\(a\)](#) and [3\(c\)](#); also see [Figure 2](#)). Like soil texture, the development of soil color also reflects many soil-forming processes. In one very common environment (well-drained and oxidizing conditions), certain soil horizons (especially the B horizon) become redder, or 'rubified.' This is most obvious if the soil parent material is one of the more abundant, typically pale brown soil parent materials with abundant quartz and feldspar (e.g., granite, many sandstones, and some metamorphic rocks). The principal soil-forming process involved is the oxidation of ferrous, divalent Fe to ferric, trivalent Fe, which typically precipitates as various iron oxyhydroxides (hereafter referred to as Fe oxides) that are generally reddish to reddish orange or reddish brown in color (e.g., hematite, goethite). A large body of literature provides explanations of the processes of chemical reduction and oxidation (chemical reactions that involve electron transfer and changes in valence state), solid-state transformation, and dehydration that ultimately produce these minerals (cf. [Schwertmann, 1994](#)). In relatively warm, oxidizing soil environments, hematite (typically red) is ultimately the thermodynamically favored mineral, whereas cooler temperatures often favor goethite formation (brown or yellow). This implies that soil Fe oxide mineralogy, which in turn is strongly correlated with soil color, should at least partly reflect processes that are in turn strongly related to climate (see below). But studies of soil morphology and soil Fe oxide mineralogy also show that the

relative content of hematite is also correlated with a degree of redness, which in turn may be related to the type of initially formed, poorly crystalline iron mineral. The accumulated mass of Fe oxides in soils is both time and climate dependent (Birkeland, 1999; Schwertmann, 1994), that is, soil color reflects processes clearly strongly related to climate, but that evolve over time.

Soil Morphology Studies and the State Factor (CLORPT) Approach

The climate in which a soil is forming or has formed is an important 'factor' that strongly influences the types, rates, and relative importance of various soil-forming processes and their relationship to different morphological properties. For example, the process of soil infiltration is closely related to the

timing, duration, and magnitude of rainfall, as well as soil temperature, humidity, and plant canopy characteristics, all of which are directly related to or essentially define the climate of a given area. Climate, however, is only one 'factor' that has a direct influence on processes of soil formation. Several centuries of soil research show that a large majority of literally hundreds of soil-forming processes can be linked in very fundamental ways to five principal 'factors.' In addition to climate (C), they include 'organisms' (O), perhaps better identified as the 'biotic' factor; 'relief' (R), or sometimes called the topographic factor; 'parent material' (P), the type of materials from which the soil has formed; and 'time' (T), or the duration of time over which the soil has formed (Jenny, 1941). Some aspects of soils cannot be easily evaluated using only these factors (e.g., spatial variation in soil development that reflect landscape evolution), but in most cases these five factors are the most critical ones, and they have come to be popularly known as 'CLORPT.' Birkeland (1999), Holliday (2004), and Schaetzl and Anderson (2004) and other researchers discuss criticisms of this approach and the recent emergence of other conceptual approaches in pedology; nevertheless, a large body of literature demonstrates the enormous impact the CLORPT approach has had in many Quaternary studies.

The real power of the CLORPT approach lies in its remarkable ability to elucidate the relative impacts of these five factors on soil formation. This is achieved through careful selection of groups of soils in circumstances such that the influences of one factor can be isolated as varying, while the others are essentially held 'constant' (Birkeland, 1999; Buol et al., 1997; Jenny, 1941). To identify differences that are related to soil age, a 'soil chronosequence' is established, and the time-dependent change in soil morphology (or a given property) is called a chronofunction (Figure 4). A large number of studies describe

Figure 1 Schematic diagram of an idealized soil profile that exhibits a vertical sequence of soil horizons. Reproduced from The Soil Survey Staff (2006) Soil – Fundamental concepts. *Soils – Tools for Educators*, version 3.0 National Soil Survey Web Page. Lincoln: National Soil Survey Center, USDA-NRCS. <http://soils.usda.gov>.

Figure 2 A soil profile with a clay-enriched and reddened 'argillic horizon.' The horizons consists of an A horizon (0–7 inch.), and E, B/E, and Bt horizons from 11 to 33 inch. depth. Well-developed structure in this horizon is indicated by the strongly expressed blocky 'peds' that are outlined by cracks. Well-expressed A and E horizons over the argillic horizon are also evident. The base of the B horizon and top of the C horizon is at a depth of 38 inch. Scale in feet. From the SSSA Marbut Slide Collection (1968).

Figure 3 Soil materials with strongly contrasting soil colors. (a) Reddish brown (2.5 YR 5/4) peds from a B horizon in a very strongly developed soil formed in alluvial fan deposits in the Transverse Ranges, southern California. (b) Olive yellow (2.5 Y 6/6) B horizon in alluvial terrace deposits in the Transverse Ranges, southern California. The olive color of the soil reflects the presence of abundant chlorite in the parent materials, a mineral common in certain types of schists, a type of metamorphic rock. Scale in tenths of meters. (c) Strongly contrasting soil colors in a soil forming on the lower slope of a glacial moraine in New Zealand. The dark colors reflect the presence of humus, the reddish colors reflect the presence of oxidized iron-bearing iron oxyhydroxides, and the pale colors reflect the loss of iron oxides and humic materials by various types of leaching processes common in a humid, but seasonably cool climate. Scale in tenths of meters. Photograph by Bruce Harrison.

Figure 4 A suite of alluvial terraces associated with the North Fork of the San Gabriel River, San Gabriel Mountains, southern California. The ages of the terraces shown range from only a few centuries old (1) to a hundred thousand years old (4). Older eroded topography above terrace 4 is associated with a several hundred thousand year old terrace that is more well preserved elsewhere in this area. The soils present on each of these terraces would constitute a soil chronosequence, and changes in the development of selected properties of these soils would constitute a chronofunction, given the generally similar alluvial parent materials, topographic position, and vegetation of these soils.

soil chronosequences in various climate regimes, parent materials and landforms, and the mathematical nature of the chronofunctions (Birkeland, 1999; Bockheim, 1980). To show the influence of climate on soil development, a 'soil climosequence' is established, which generates 'climofunctions.' Similarly, 'biosequences,' 'toposequences,' and 'lithosequences' (and their associated factor-related functions) can be developed in appropriate circumstances.

Considering the key research questions and goals of Quaternary science, the most typical application of morphological studies of soils in Quaternary studies reflects the desire to use soils to provide important deposit and landform age information or paleoclimate/paleoenvironmental information. Therefore, soil chronosequence and climosequence studies have

been of particular interest to Quaternary scientists, although toposequences, not discussed in this article, are also used in studies of landform development. Studies of soil morphology and associated Quaternary sediments and landforms have been conducted in virtually all climatic regimes (cf. Birkeland, 1999; Buol et al., 1997), but a substantial fraction of soil morphology studies associated with chronosequence and climosequence development have been conducted in the temperate, arid, and semiarid regions. The discussion below mainly focuses on these latter studies.

There are some unavoidable problems with the CLORPT approach. An important one is that the CLORPT factors are not independent, but instead are often somewhat too strongly interdependent, such as climate and organisms. Therefore, it is sometimes difficult to determine the relative degree of importance with respect to two factors and their respective influence on the formation of a given property. Another important problem, especially in the study of Quaternary soils, is the global climate changes on timescales ranging from tens to hundreds of thousands of years (interglacial-to-glacial changes) to shorter timescales. Some of the larger climate changes of the Quaternary almost certainly caused changes in the rates, processes, and magnitudes of soil development through time. Therefore, there can be no chronofunctions that are completely 'time dependent,' that is, the increasingly older, pre-Holocene soils in a chronosequence will almost surely have morphological properties that must unavoidably reflect both the results of climate-change-induced processes and straightforward age-dependent properties. Such soils are called 'polygenetic' soils and they are abundant in many landscapes.

There may also be relatively few (if any) true climosequences, because time-dependent changes in soil development may inevitably lead to dramatic and rapid changes in soil development (which may be expressed as changes in morphologic expression) as 'soil thresholds' are crossed, potentially after varying times of soil development and reflecting different fundamental changes in soil-forming processes (Muhs, 1984). These problems are not insurmountable, as discussed in

Birkeland (1999), Holliday (2004), and elsewhere, and we need to be aware of these complexities. Significant increases in our understanding of the impact of climate changes on soils and their associated landscapes have increased our ability to isolate the most strongly time-dependent soil-forming processes and associated properties, and analogously, climate-related properties.

Relations Between Soil Morphology and Soil Age

Although there are a very large number of soil morphological properties, a relatively small number of them have proved especially useful in Quaternary studies. This partly reflects the fact that the relations between only a small handful of morphological properties, their related soil-forming processes, and their connection to CLORPT are reasonably well understood. For example, the origin and evolution of soil carbonate morphology is generally well understood with respect to age and climate, whereas the origins of soil structure with respect to climate and age are more complex and less well understood. Also, some morphologic properties are generally easier to quickly recognize and objectively characterize in the field than others (Reheis et al., 1989). There are many other seldom-used properties such as pore and root size, type, and density, but they are not unimportant and should also be included as possible in soil descriptions. For example, soil pore type, frequency, and spatial relationships (e.g., connectedness) critically affect the internal movement of soil water, certain soil materials, and soil gases.

An excellent opportunity to maximize the relationship between soil age and soil morphology using the CLORPT approach is provided by landscapes with flights of terraces of fluvial origin (see Figure 4). The composition of the alluvium, the topography of the surfaces and their vegetation communities are often broadly similar. Soils on pre-Holocene terraces have been subjected to different climate(s) earlier in the Quaternary, but some strategies can be used to recognize, and therefore explicitly consider, the probable impacts of the former climate regimes on soil-forming rates and processes. Other groups of landforms have also proved to be useful for the purpose of development of chronosequences, including lava flow surfaces (cf. McFadden et al., 1986), dunes (cf. Muhs et al., 1996), alluvial fans (cf. Harden et al., 1991), glacial moraines (cf. Burke and Birkeland, 1979), and marine terraces (Chadwick et al., 1990). Some landforms are generally unsuitable for chronosequence studies, such as those dominated by surface erosion as a process in their development. Examples include 'pediments,' which may require as many as several million years to form in certain rock types, and landforms characterized by inherently moderate to very steep gradients (e.g., hill slopes). Strong soils may form in loess, but continued episodes of loess accumulation slowly bury previously developed soils, promoting the development of a complicated, cumelic, probably polygenetic soil profile (Muhs and Bettis, 2003), making it difficult in most circumstances to directly use the CLORPT approach.

In addition to a favorable suite of landforms, recognizing and isolating strongly time-dependent properties are facilitated when the related soil-forming processes are generally well

understood. When this is the case, the potential influences of climate and/or changes in climate on a soil-forming process can be explicitly considered, and the impact on the process rate and associated property understood. A good example is provided by the strongly time-dependent changes in soil carbonate morphology, first described formally by Gile et al. (1966) and the subject of numerous subsequent studies (Birkeland, 1999). These studies provide a robust understanding of the key processes that control the rate, magnitude, and depth of carbonate accumulation, even enabling the development of numerical models for the simulation of calcic soils in different climates and parent materials (McFadden and Amundson, 2002).

Soil morphology does provide, however, a powerful means of determining 'relative ages'; for many types of landforms and it can also be used to temporally correlate landforms ('correlated ages'; Colman et al., 1987). Deposit or landform ages based on soil morphology can also be used in some favorable circumstances to provide provisional age-range estimates for certain landforms and deposits. One benefit of this is that such estimates can be used as a basis for selecting the most appropriate numerical dating technique. They may also be used to critically evaluate the results of more recently developed, but often difficult to interpret geochronological methods (e.g., cosmogenic radionuclide (CRN) dating).

Selected Examples of Time-Dependent Changes and Applications in Quaternary Studies

The development of soil chronosequences associated with different types of landforms shows that certain soil properties change systematically in strongly time-dependent ways in many different climatic settings. In most cases, key soil morphological properties require a minimum of a few centuries to millennia to form, and in some cases may require tens to hundreds of millennia (Birkeland, 1999). Chronosequence studies also show that rates of property development may vary considerably in different climate regimes. Examples of Quaternary studies that have greatly benefited from the use of soil morphology include the impacts of climate and climate change on fluvial systems (cf. Bull, 1991), eolian processes (cf. Muhs et al., 1996), and slopes (cf. McAuliffe et al., 2006); the impact of active tectonics on landscapes ranging from the fault scarp scale (Eppes et al., 2002; Machette, 1978; Menges, 1990), to the much larger scale of nearly continental scale, arc-related mountain belts (Pazzaglia and Brandon, 2001). Soil research has also been applied in important ways in archaeological research (Holliday, 2004; Waters, 1992) and landscape ecology (McAuliffe, 2003). Happily, the increased understanding of landscape evolution partly assisted by soil morphology studies has often subsequently provided important new insights into soil-forming processes.

Soil color is one soil property that, in many environments, changes in a strongly time-dependent manner. The Munsell Soil Color Chart is the most widely used means of determining soil color semiquantitatively. Soil color varies greatly, but many studies have shown that one of the strongest time-dependent changes in soil color, ranging from tens to hundreds of thousands of years, is the reddening of soils, the result of the accumulation of ferric iron oxyhydroxides such as

hematite (Schwertmann, 1994; Figure 5(a)–5(d)). Often the reddest color occurs in the most well-developed part of the soil B horizon. Once a chronofunction for soil ‘reddening’ has been developed in a certain region, it may be one of the most important, relatively easily measured soil properties that can be used as a basis for correlation of associated surfaces or deposits or, in appropriate circumstances, estimated age ranges.

Other properties of the soil B horizon that sometimes also change in a strongly time-dependent fashion are soil clay content, the number and thickness of soil clay films, and the expression of soil structure. The thickness of the soil B horizon (in which the strongest expression of these soil properties nearly always occurs) has been shown to change in a very strongly time-dependent fashion. The rate of change of B horizon thickness and other soil properties can be expressed mathematically in a few different ways, such as exponential or power functions.

Many explanations have been provided to explain these different mathematical trends. For example, the generally linear rate of soil carbonate accumulation over time spans of tens to hundreds of thousands of years may be attributable to the main process by which this material accumulates in soils (discussed below), the continual incorporation of calcium present in windborne dust or dissolved in rainwater. In contrast, a curvilinear function may reflect time-dependent changes in the accumulation of soil materials that mainly accumulate by *in situ* chemical weathering, a process that in many circumstances depletes the supply of the associated parent materials.

Figure 5 The increasingly redder colors of the B horizons of soils in a soil chronosequence associated with alluvial and fan surfaces of the Santa Catalina Mountains, near Tucson, Arizona. Age ranges of the soils are estimated on the basis of the similarities of the degree of their soil property development with that observed in other soils of the southwestern United States that have formed in a similarly arid, desert climate. (a) 1–5 ka old (Holocene); (b) 10–25 ka old (latest (?) Pleistocene soil); (c) 50–100 ka old (late Pleistocene); (d) 100–500 ka old (late middle (?) Pleistocene).

A few researchers also have proposed that some unexpected trends may be the result of past times during which global climate was uniquely favorable to rapid soil development (see discussion below). Field-based Quaternary studies show, however, that in some cases the cause of the development of unusually thick B horizons in some settings does not require remarkable changes in soil development rates or the unpredictable ‘emergence’ of some ostensibly anomalous property. For example, studies of Harrison and his colleagues (1990) showed that even very small contributions of material from hill slope sources above and well distant from a terrace tread can dramatically increase their B horizons to thicknesses double or more than those associated with topographically isolated surfaces. This is accomplished while the soil A horizon is converted slowly to a B horizon, in a fashion somewhat similar to that proposed for soils in loess (Busacca, 1989; Muhs and Bettis, 2003). Thus, substantial differences in the rate of change of a B horizon can be caused by seemingly subtle differences in surface slope, distance to slope sources, differences in composition of materials (including soils) on these slopes, and processes of bioturbation.

The time-dependent change in soil carbonate morphology is the one chronofunction probably most well-known by geoscientists who work in arid and semiarid regions (Figure 6(a) and 6(b)). Other studies also show that carbonate coatings on gravel (also called rinds) also thicken in a strongly time-dependent fashion, at least in some apparently favorable, but not particularly well-understood circumstances (Amoroso, 2006; Treadwell-Steitz and McFadden, 2000; Vincent et al., 1994). Chronosequence studies have highlighted the essential role that desert dust plays in the accumulation of increasing mass of carbonate, silica, and gypsum and its morphological

Figure 6 Expression of soil carbonate morphology in soils of different ages associated with alluvial fan deposits of the northern flank of the San Bernardino Mountains. (a) A relatively young ‘Holocene’ soil in gravelly alluvium showing ‘stage 1’ morphology. Note the carbonate coatings visible as the white areas on the bottom sides of the boulders between a depth of 20–50 cm. This is the most common expression of this morphologic stage in gravel-rich parent materials. (b) Old ‘Pleistocene’ soil, showing ‘stage 4’ morphology (massively cemented, strongly indurated horizon). Laminar morphology is also a hallmark of this advanced stage of carbonate accumulation and is visible at a depth of 45–50 cm. A diagnostic horizon with these features is called a ‘petrocalcic’ horizon, which, in this case, is buried by a much younger alluvial deposit, which implies loss of a once overlying B horizon by erosion of the fan surface (Eppes, 2002). Photograph by M. Eppes.

evolution (Harden et al., 1991). In some landscapes, the deposition of dust also greatly influences the evolution of many spatially extensive landforms and associated surficial deposits in arid regions. With relatively high rates of dust deposition, desert 'loess' deposits may form, whereas lower rates allow accumulation of the dust below the soil surface into the B horizon, which favors stronger soil development (Muhs and Bettis, 2003). In drier parts of deserts, these processes also favor desert pavement, because the fine material is trapped below any large, stable rocks, which stay at the surface as the slowly accumulating fine material is converted to soil.

In many landscapes, soils are rarely older than the Quaternary, usually younger than Middle Quaternary, and are often of Holocene age. Minimally developed soils may also dominate landscapes that have been tectonically very active during the Quaternary. In these landscapes, steep slopes, generated by active tectonics, favor high erosion rates and active accumulation of sediment on floodplains and often extensive alluvial fans. The soils in both cases are weakly developed, either because erosion removes the sediments faster than soils can form, or the deposition of sediment is too rapid to allow soils to form. Alpine glaciation is typically more extensive in the highest parts of mountain ranges, extending to lower elevations with increases in latitude. Many of the soils in landscapes dominated by glacial landforms reflect recent glaciations of the Quaternary. Only in the most tectonically stable regions in favorable latitudes do processes favor continued soil development (or at least preservation) over millions of years on geomorphically stable landforms. The best studied of these are very old, pre-Quaternary, highly polygenetic soils of Australia. These soils have a complicated morphology that reflects soil development over several million years under numerous global climate changes. They also reflect major changes in the climate of Australia that were caused by substantial changes in this continent's latitude associated with the northward movement of the Australian plate during the Cenozoic (Birkeland, 1999). Such old, complex soils are extremely rare and not typical of most continents.

Relations of Soil Morphology and Climate

As discussed above, a basic process that drives much of soil development is weathering, and the interaction of soil with infiltrating soil water is one of the underlying causes of many types of weathering processes. The most important soil-forming factor that dictates how much and when water will infiltrate and interact with soil solids, soil pore water, and the soil atmosphere is the climate factor. Because a very important goal of many Quaternary studies is to understand how climate changes affected the Earth during the Quaternary, the strong soil-climate relationship has attracted the interest of many Quaternary scientists. One important question that is asked concerns which aspects of soils can be evaluated specifically for the purpose of obtaining climate proxy information. Put another way, information from soils is sought that can be used to reconstruct quantitative aspects of the climate during some past time.

Some answers to these questions have been provided through studies of 'climosequences' and derived climofunctions using the CLORPT approach. Such studies have demonstrated

that there is a significant relation between the development of certain important diagnostic horizons and climate. For example, a very strongly chemically altered B horizon enriched in certain clay minerals, iron and aluminum oxides, and virtually devoid of the original parent materials (the oxic B horizon) forms only in generally seasonably warm, generally humid climate. In contrast, a B horizon enriched in calcium carbonate, a relatively soluble mineral, usually only forms in a generally arid or semiarid climate (a calcic horizon). The Mollic A epipedon usually forms in a subhumid to semiarid climate under grass, whereas usually other types of surface soil horizons typically form in different climate and vegetation settings (Buol et al., 1997). There are also important relations between soil mineralogy, soil chemistry, and climate (Birkeland, 1999). For example, soil formation in a generally 'humid' climate often favors the formation of kaolinite and aluminum oxyhydroxides, but not smectite, a clay mineral typical of soils of drylands. The rate of Fe oxide accumulation increases more rapidly for soils forming in progressively more humid climates in southern California. Certain aspects of B horizon morphological properties reflect B horizon mineralogy, partly reflecting these climate-soil property relationships.

Quaternary scientists, however, seek relatively 'high-resolution' climate proxy information, that is, they seek information such as the annual quantity and seasonal timing of rainfall or annual variation in air temperature. Climosequence studies show that although climate-soil relationships can be observed, these relationships are complicated in many respects, so that soil features provide mainly 'low-resolution' proxy data. Recalling the example concerning clay content discussed above, a single morphological property is the result of many underlying soil-forming processes, and these processes are affected by different aspects of 'climate' in potentially very different ways. For example, the magnitude of chemical weathering may increase in increasingly humid climate regimes, but such soils in the landscapes are also subject to eolian dust and its incorporation (cf. Muhs et al., 1990). The clay in this dust may well have formed in an entirely different kind of climate, thereby greatly complicating efforts to correlate B horizon mineralogy and overall clay content with climate type. In other words, there is no simple climate 'transfer function' that enables one to equate, for example, soil clay percent or mineralogy as a function of depth with a region's annual (or monthly) rainfall, temperature, relative humidity, actual and potential evapotranspiration, and wind velocity and/or direction.

One important aspect of soil carbonate morphology that does reflect a moderately good relation with 'climate' is the depth of carbonate accumulation and mean annual rainfall. Since Arkley (1963) first formally recognized this relation, many more recent studies have generally corroborated that relationship (cf. Retallack, 1994). The climate-depth relation is complicated and not as strong as might otherwise be expected because many soil-forming processes that are linked to 'climate' in varying ways determine the depth of soil carbonate accumulation. Numerical models of carbonate accumulation in soils have helped elucidate the relationship between carbonate morphology and climate (McFadden and Amundson, 2002). Model results show, for example, that climate changes during the Quaternary should have significantly changed the rate and depth of carbonate accumulation in soils,

and the morphology of some calcic soils seems to reflect changes simulated by such models. These models also show, however, that the specific changes in rates and depths of carbonate accumulation would depend on several important variables, some of which are difficult to specify quantitatively. No model yet exists that is capable of simulating the carbonate accumulation and morphological changes in natural settings, and until one does, carbonate soil morphology cannot be used as a source of high-resolution climate proxy data.

Morrison (1967) has argued that during certain periods of the Quaternary when climate was relatively warm (e.g., interglacial or interstadial periods), conditions were especially conducive for chemical weathering and very rapid soil development. He calls such periods 'soil-forming intervals' and the associated soils, 'geosols.' Some Quaternary scientists have accepted many of the key arguments that make up the conceptual basis of geosols, and, given the presumed circumstances under which they form, their identification in Quaternary sequences would have important climatostratigraphic significance (Catt, 1986). Many other studies strongly indicate, however, that the concept is very problematical (Birkeland, 1999).

Soil Morphology and Quaternary Deposits

Some soil morphology studies in the Quaternary sciences lay a strong emphasis on the recognition and interpretation of buried soils (Figure 7). The recognition of buried soils is

Figure 7 A well-developed buried soil in alluvial terrace deposits associated with Duncan Canyon Wash, a river associated with a drainage basin of the south flank of the San Gabriel Mountains, southern California. The top of the buried soil is indicated by the arrow. Geologist's hammer for scale.

particularly important with respect to the development and interpretation of stratigraphic sequences in Quaternary sediments. For example, the presence of a buried soil in a sequence of Quaternary sediments unambiguously demonstrates the presence of a stratigraphic unconformity, which in turn shows that the surface associated with the buried soil was geomorphologically stable over the period of time needed to allow the soil to form. Such soils can, for example, reveal how both local and regional base level has changed in the past, and the pattern of the buried soils may then help to determine the underlying causes of these changes. The degree of development of the buried soil also can be useful to estimate the duration of time over which it formed; in many cases, buried soils can be used as a basis to temporally correlate deposits over relatively large areas. Many times there is little evidence other than the presence of buried soils to allow correlation of gravelly non-marine deposits (e.g., those typical of alluvial fans and other high-energy depositional environments) since they often lack fossils or other datable materials.

There are some problems or disadvantages with respect to the recognition and interpretation of buried soils. Some features formed many meters to tens of meters below the ground surface by processes in the vadose (aerated) zone or groundwater table fluctuations may strongly resemble some features formed through soil development (Figure 8). Such misidentifications could easily lead to serious errors in the interpretation of the Quaternary history of a given region and so it is essential to avoid such errors. Also, the geomorphic processes that cause the burial of landscapes often lead to erosion and/or modification of the uppermost horizons of soils of those landscapes, thereby significantly diminishing the extent to which they can be used to provide the information often sought by Quaternary scientists.

Figure 8 Massively calcite-cemented alluvium, Marble Mountains, Mojave Desert in southern California. This material resembles an advanced stage of soil carbonate morphology, but it is formed by processes largely unrelated to soil development, including bank infiltration of stream water that contains large concentrations of dissolved calcite. The process occurs during large floods in these normally dry washes, which with time causes calcite cementation of the initially very porous gravelly materials along the bank with calcite. Field hand shovel for scale.

Quantitative Evaluation of Soil Morphological Development: Soil Profile Indices

The determination of a soil profile index, or profile development index (PDI), enables conventional soil morphological data (e.g., consistence, Munsell soil color, soil fine earth texture) to be transformed to a 'numerical' form. This is another way to quantitatively evaluate soil morphological information, besides laboratory analysis of soil materials. The method used most frequently is that developed from studies of soils in unconsolidated alluvial deposits of Quaternary age located in the San Joaquin Valley, California (Harden, 1982). Indices are calculated by rather arbitrarily assigning numerical values to different categories of properties (e.g., change in rubification, soil consistence, structure or increases in clay film thickness and content). Determination of both horizon and the PDI is made on the basis of quantitative comparisons of observed horizon property values with both those of the parent materials and a 'maximum value' for the given property.

Many studies show that this method is useful for highlighting strongly time-dependent trends in the morphological development of a chronosequence of soils (Figure 9), although PDI-derived age estimates should not be equated with conventional numerical ages. In some circumstances, the use of the PDI may be problematic. For example, the maximum rubification hue is 10R (pale red to red). This is a color that can ultimately form in soils that are over a million years old, but that have been subject to a soil moisture regime that has never (or only very rarely) favored chemically reducing conditions. These conditions would terminate the continued

Figure 9 The change in the Profile Development Index values observed in two soil chronosequences in California from the Cajon Pass area of the Transverse Ranges and the Merced area of the Central Valley. The crosses show the estimated age ranges of the soil parent materials and the estimated range in the associated values of the PDI. The colored regions show the statistically determined range of uncertainty associated with the ordinary least-squares linear regression.

Figure 10 (a) A typical desert pavement and the soil profile beneath it formed on a late Pleistocene basaltic lava flow in the Cima Volcanic Field, Mojave Desert, California. Field knife for scale. (b) Schematic diagram depicting the stone pavement, soil, and underlying basalt flow bedrock. Age determination of the flow based on Ar 40–Ar 39 dating is 212–239 ka (unpublished age date; New Mexico Technical Institute Geochronology Laboratory, Heizler, 1999); the pavement clasts, from CRN dating, range from 140 to 180 ka (Poeths et al., 1998). The ages of the surface pavement rocks are consistent with pavement genesis via entirely subaerial, mechanical weathering of surface materials formed during flow emplacement. The ages of the uppermost materials based on thermoluminescence (TL) dating are much younger (5 ka in Avk; 13.5 ka in Bk; McFadden et al., 1998). The much younger TL ages are consistent with the morphologic development of the soil that immediately underlies the much older, darkly varnished stone pavement, illustrating how soil development faithfully reflects both its age and the desert surficial processes.

accumulation of iron minerals that promote strong rubification, or even cause their loss entirely from the soil, and such conditions may arise in the strongly weathered soils of landscapes with climate regimes that are very humid compared to California. Therefore, in a region associated with a relatively humid climate, it would be inappropriate to use the maximum value for rubification in the determination of the PDI of soils of that region. Also, many aspects of soil descriptions are unavoidably subjective and highly dependent on the experience and skills of the person describing the soil. Thus, a PDI incorporates this subjectivity. Finally, the numerical data assigned to the property categories represent ordinal-scale data. Calculation of the PDI essentially upgrades this data to interval-scale data which in turn is used in the determination of various statistics; this, however, is also problematic because ordinal-scale data cannot be used in the calculation of such statistics.

The Future of Soil Morphology Studies in Quaternary Science

Soil morphology studies have proved to be very useful in diverse areas of Quaternary research. The recent development of new methods for quantitative analysis of soil materials and numerical models of soil development that have helped elucidate the nature of soil-forming processes provide new opportunities for the study and interpretation of soil morphology. The development of new geochronological methods provides additional means to independently determine the numerical age of soils, which in some places like deserts was very difficult. CRN age dating (or 'surface exposure' dating) is an example of a method that is particularly useful in the dating of soils and surface features (Gosse and Phillips, 2001; Wells et al., 1995).

The emergence of some of these new methodologies has also somewhat diminished the use of soil morphology in some areas of Quaternary research. Many Quaternary scientists continue to recognize, however, the utility of soils in their research,

because they recognize that the character of soil morphologic development yields key insights into many processes of landform evolution on both short and long geologic timescales. Studies of the origin and evolution of extensive rocky desert surfaces are a good example of this. Studies of soil morphology help show that desert pavements form very differently than was thought for many decades (McFadden et al., 1987, 2005; Wells et al., 1995; Figure 10). CRN dating provides additional support for the new model of desert surface formation, because this method can be used to determine the 'first exposure ages' of the rocks in the pavement. The morphology of the soils immediately beneath the pavement, however, reflects the processes that have most recently dominated their development in the past few thousands of years, which CRN ages alone could not reveal. Similarly, on some land surfaces that might otherwise appear to be geologically young, the presence of even small fragments of soil materials that can only form over long periods of time (e.g., massively cemented soil carbonate or deeply rubified, clay-rich, near-surface B horizons associated with very different soil parent materials) reveal their true antiquity.

CRN dating of surficial deposits and soils can provide important information about basin-wide weathering and erosion rates, but soils also progressively incorporate eolian materials, so obtaining meaningful CRN ages in such circumstances may prove difficult, if not impossible. If soil chronosequence information is available, however, the soil morphology will almost always accurately reflect at least a general age range for the associated surface or deposit. Moreover, obtaining the CRN dates is ultimately a very expensive proposition; the description and evaluation of soils is not.

A soil is a highly complex natural system that probably becomes even more complex with increasing age, as it is periodically and unavoidably subjected to global climate changes of various magnitudes. These changes alter soil water balance and hydrology, plant communities, eolian accumulation rates and composition, and the types and rates of other important surficial processes that influence soil development (e.g., rate

Figure 11 Two fundamentally different evolutionary pathways of soil and surface development in gravelly, alluvial parent materials in different climate regimes. The very different morphologic features of these soils reflect the different types and rates of various soil-forming processes and surficial processes that culminate in profoundly contrasting soils and landforms.

and magnitude of infiltration of rainwater relative to surface runoff, which strongly influences the nature of flow over the soil surface). Studies of some desert soil chronosequences in the American Southwest that have revealed very anomalous, poorly understood patterns of soil development may well reflect this soil system complexity (Figure 11). Perhaps these 'anomalies' actually do represent certain characteristic aspects of soils that are better understood as dynamical, complex systems, such as emergent properties, nonlinear behavior, or self-organization (cf. Sprott, 1997). The CLORPT approach, which has proved its great usefulness in soil morphological research in Quaternary sciences for nearly 70 years, may be the one used in those future studies that answer these questions.

Biogeochemical Role of Dust in Quaternary Climate Cycles

K E Kohfeld, Simon Fraser University, Burnaby, BC, Canada

Introduction

The geologic record reveals to us that the activity of dust on Earth has varied considerably through time, in response to large reorganizations of the climate system. For example, major increases in the deposition of dust downwind of Asia began 6 to 2 Ma, mostly likely associated with the uplift of the Himalayas and the subsequent evolution of the East Asian monsoon system (e.g., [An et al., 2001](#)). We see a similar intensification of the dust production downwind of Africa with the onset of Northern Hemisphere glaciations and cooling of North Atlantic surface temperatures after 2.8 Ma ([DeMenocal, 2004](#)).

Over the past 2.6 My, the Earth has gradually transitioned into a period of regular, glacial–interglacial cycles, and the global dust cycle has developed in pace with it. Over the past 800 000 years, the Earth's dustiest periods have coincided with the periods of maximum ice sheets and minimum temperatures, which come every 100 000 years. Well-constrained records of dust deposition in marine sediments from the Pacific Ocean ([Hovan et al., 1991](#); [Stancin et al., 2008](#); [Winckler et al., 2008](#)), the equatorial Atlantic and Indian Oceans ([Clemens and Prell, 1990](#); [DeMenocal, 2004](#)), the mid-latitude South Atlantic Ocean ([Martinez-Garcia et al., 2009](#)), in loess deposits on the continents (e.g., [Ding et al., 1994, 2001](#); [Guo et al., 2002](#); [Karimi et al., 2011](#); [Muhs et al., 2003](#); [Rousseau et al., 2011](#); [Schmidt et al., 2011](#); [Tófaló et al., 2011](#); [Újvári et al., 2010](#); [Zech et al., 2011](#)), and in ice at remote locations of the polar ice caps ([Lambert et al., 2008](#)) suggest that these cycles of dust deposition occur in a very similar fashion throughout the world during the Quaternary ([Figure 1](#)).

Superb records of changes in dust deposition have been retrieved from Antarctic ice cores over the past 800 000 years ([Lambert et al., 2008](#)). A close examination of these records suggests that fluctuations in dust, atmospheric trace gases, and temperature exhibit remarkably cyclic behavior, suggesting that dust is a key feedback within the Earth system ([Figure 2](#)). As the Earth enters an Ice Age, dust concentrations begin to rise only after temperature and CO₂ concentrations have begun to drop toward their full glacial conditions. In other words, the dust cycle is invigorated about half-way through the Earth's descent into glaciation, and thus may behave as some form of feedback that could amplify glacial conditions ([Kohfeld and Ridgwell, 2009](#)).

Global compilations of dust deposition have been used as a means of evaluating our ability to simulate glacial–interglacial changes in the dust cycle using Earth system models, and until recently focused on the Last Glacial Maximum (LGM) period, approximately 21 000 years ago ([Figure 3](#)). During the last Ice Age, dust deposition increased by approximately two to four times globally, and by as much as 20 times in the polar regions when compared with warmer interglacial periods ([Kohfeld and Harrison, 2001](#); [Kohfeld and Tegen, 2007](#); [Mahowald et al., 2006a](#); [Rea, 1994](#)).

Dust as a Link Between Land, Atmosphere, and Sea

These geologic records demonstrate that dust deposition has changed dramatically in the past, and may have behaved as a rhythmic feedback that responds to changes in the Earth's climate, and subsequently impacts different parts of the Earth system. Dust is emitted from the land surface in response to changes in land cover, but also in response to climate, which controls changes in temperature, precipitation, wind, and soil moisture. Dust enters the atmosphere where it affects the regional and global radiative budget – and therefore climate – before it is deposited. Dust deposition delivers important trace elements and nutrients to land surfaces and has contributed to long-term soil formation and development throughout the Quaternary in several parts of the world ([Chadwick and Davis, 1990](#); [Chadwick et al., 1999](#); [Muhs, 2001](#); [Muhs et al., 1990, 2010a,b](#); [Swap et al., 1992](#); [Vitousek et al., 1999](#)). When dust is deposited over the sea, it may act as a fertilizer to marine organisms, influencing ocean carbon sequestration and the production of several trace gases and chemical constituents that can affect climate.

We can also anticipate that dust will continue changing in the future, with natural and human-induced perturbations to climate and the Earth's land surface. Our ability to simulate these changes with dust cycle models can be evaluated based on comparisons between Earth system models and the geologic record, and help us to assess what role dust could play in modifying future climate and biogeochemical systems. In the past 12 years, Quaternary dust observations have been used as a means of validating dust cycle models, and have helped to quantify the impacts of changes on dust on Quaternary climate and carbon cycles ([Cakmur et al., 2006](#); [Kohfeld and Ridgwell, 2009](#); [Mahowald et al., 1999, 2006a](#); [Reader et al., 1999](#); [Takemura et al., 2009](#); [Tegen et al., 2002](#); [Werner et al., 2003](#)).

Land-Dust Emissions

Simulated estimates of total modern global dust emissions range from 1019 to 3321 Tg year⁻¹, with optimized multimodel estimates yielding a tighter range of 1500–2600 Tg year⁻¹ ([Cakmur et al., 2006](#)). A comparison of all modeling studies suggests convergence at a value of 2000 Tg year⁻¹, although this convergence does not imply accuracy given large uncertainties associated with our ability to quantify dust emission, deposition, and particle size characteristics at a global scale ([Shao et al., 2011](#)). Several factors influence the emission of dust from the land surface. These factors include (a) the characteristics of the soil surface, including surface roughness, particle size, soil mineralogy, (b) soil moisture, (c) soil availability, (d) the degree of vegetative cover, and (e) the degree of particle cohesion, crusting, or cementation. Once these basic conditions are met, dust emissions occur when the wind speeds exceed a threshold

Figure 1 Dust deposition on land, ocean, and ice surfaces all around the globe has changed in pace with the ice ages over the course of the Quaternary. Data shown here represent a variety of proxies for dust and include (moving clockwise from the top): Calcium concentrations ($\mu\text{g kg}^{-1}$) from the Greenland ice sheet GRIP core (De Angelis et al., 1997); aeolian fluxes ($\text{g cm}^{-2} \text{ka}^{-1}$) calculated for the Zhaojiachuan (35.45°N , 107.49°E , 1250 m) and Lingtai 35.04°N , 107.39°E , 1350 m) loess sections from the central China Loess Plateau (Sun and An, 2005); Iron fluxes (green circles) and ^{230}Th -normalized iron fluxes (white circles, $\text{mg m}^{-2} \text{year}$) from deep-sea core ODP Site 1090 (42.91°S , 8.9°E , -3700 m) in the South Atlantic Ocean (Martinez-Garcia et al., 2009); nonsea salt Calcium fluxes to the EPICA Dome Concordia ice core in East Antarctica (Lambert et al., 2008); normalized ^{230}Th fluxes from deep-sea core TT013-PC72 (0.11°N , 139.4°W , -4298 m) in the Equatorial Pacific Ocean (Winckler et al., 2008); and dust fluxes to ODP Site 108-659A (18.08°N , 21.03°W , -3082 m) in the Equatorial Atlantic Ocean (Tiedemann et al., 1994). Glacial and cold stadial periods are shaded in gray. Central figure shows average atmospheric dust concentrations taken from Jickells et al. (2005).

velocity that allows soil particles to be mobilized. A look at satellite images demonstrates that dust emissions happen today mostly in arid and semiarid regions around the world (Figure 4), in dust emission ‘hotspots’ found over lake, fluvial, and dune deposits, but also in areas of active glaciation such as Alaska (Crusius et al., 2011). The majority of these dust emission sources (63%) are located in North Africa and the Middle East, with Australia and Asia holding 11% and 8% of these hotspots, respectively (Mahowald et al., 2009).

Given that many factors controlling dust emissions are likely to change with climate (e.g., temperature, precipitation, and winds), it is not surprising that dust deposition appears to have changed throughout the Quaternary. For example, increased meridional temperature gradients at the LGM compared to today were likely to have increased the strength of the storm tracks, increasing surface winds and gustiness in some locations (McGee et al., 2010). Temperature reconstructions suggest that tropical sea-surface temperatures were approximately $2\text{--}3^\circ \text{C}$ cooler at the LGM compared to today, and the difference was as large as -2 to -6°C in certain polar regions (MARGO Project Members, 2009). Terrestrial surface temperatures were on the order of -5.5°C cooler in the tropics (Ballantyne et al., 2005) and as much as $10\text{--}23^\circ \text{C}$ lower in

Antarctica and Greenland, respectively (McGee et al., 2010). The thermal wind relationship suggests that increased glacial meridional temperature gradients were likely to be related to increased pressure gradients and intensified jet streams. These may have intensified gusts associated with cold fronts near mid-latitude sources (McGee et al., 2010). Observational evidence also supports increases in wind speeds over key regions. Evidence of increases in the median grain size during glacial periods is found near source regions such as in China (Ding et al., 2001) and North Africa (Sarnthein et al., 1981). Measurements of changes in the median grain size data cannot always be interpreted simply as changes in wind speeds. Nevertheless, analysis of model simulations also supports increases in wind speeds near glacial source regions. Analysis of extreme winds from LGM simulations suggest that the frequency of extreme wind speeds increased over key source regions in Patagonia, Asia, and Africa (McGee et al., 2010).

Changes in climate likely resulted in expanded dust source areas during the LGM for a number of possible reasons. First, given that sea level was lower by approximately 120 m (Peltier and Fairbanks, 2006), exposed continental shelves might have served as new dust sources. Some model simulations have implicated exposed shelves in high-latitude regions as contributing

Figure 2 Temperature and carbon dioxide concentrations measured in Antarctic ice cores have demonstrated tightly coupled variations over the last 800,000 years. While dust deposition exhibits a regular rhythm as well, it only increases during the later stages of each of the glacial cycles. Redrawn from Kohfeld KE and Ridgwell A (2009). Glacial–interglacial variability in Atmospheric CO₂. In: Le Quere C and Saltzman ES (eds.) *The Surface Ocean – Lower Atmosphere Processes, Geophysical Monograph Series*. AGU: Washington, DC. <http://dx.doi.org/10.1029/2008GM000845>.

Figure 3 Comparison between observed and modeled changes in dust deposition demonstrate that the Earth was two to three times dustier during the last glacial period. Reproduced from Mahowald NM, Muhs DR, Levis S et al. (2006) Change in atmospheric mineral aerosols in response to climate: Last glacial period pre-industrial, modern and doubled carbon dioxide climates. *Journal of Geophysical Research – Atmospheres* 111: doi:10.1029/2005JD006653.

to dust production (e.g., Andersen et al., 1998; Werner et al., 2003). Werner et al. (2003) suggested that exposed shelves (primarily in Australia, South America, eastern Siberia, and Alaska) may have contributed as much as 25% to the observed

increase in dust during the glacial period. Evidence suggests that lowered sea level may have enhanced potential sources for coastal sand dunes (Hanebuth and Lantzsch, 2008; Muhs et al., 2008, 2010a). Enhanced glacial sources of dust from

Figure 4 The Aerosol Index averaged from 1985 to 1990 from the Total Ozone Mapping Spectrometer (TOMS) provides a first-order approximation of where dust sources are located today (NASA Total Ozone Mapping Spectrometer Ozone Processing Team, NASA/GSFC Code 613.3, Data Product: Aerosol Index, http://toms.gsfc.nasa.gov/aerosols/aerosols_v8.html).

continental shelves are difficult to infer (Walter et al., 2000), but have been suggested for parts of Australia, South America, and Antarctica (Bigler et al., 2006; Gingele et al., 2004).

Second, in addition to climatic changes, lower CO₂ levels may also have inhibited photosynthetic activity and restricted vegetation near potential dust source areas. Several reconstructions of paleo-vegetation, lake level status, and paleo-humidity suggest that conditions during the LGM were likely more arid near source regions (see, e.g., Kohfeld and Harrison, 2001; Tjallingii et al., 2008). Vegetation reconstructions indicate that the boreal forests were greatly fragmented during the LGM across Europe, Asia, Beringia, and North America, and replaced by more cold, arid types such as tundra and steppe vegetation (Prentice et al., 2000) or by large ice sheets. Deserts in eastern Asia were expanded during the LGM (Yu et al., 2000), conditions in and near Asian dust source areas were more arid during glacial periods, and deposition was greatly increased near these sources (e.g., Ding et al., 2001). Today the highest rates of dust deposition are found downwind of North Africa, and have been shown to be two to five times greater at the last glacial period compared with interglacial periods (Kohfeld and Harrison, 2001; Ruddiman, 1997; Sarnthein et al., 1981). Provenance studies suggest that glacial and interglacial dust deposited downwind of Africa has similar sources (Cole et al., 2009; Grousset et al., 1998). Changes in dust deposition have also been primarily attributed to colder, drier, and windier conditions (Harrison et al., 2001), and recent work suggests that the Sahara and Sahel regions of Africa experienced reduced vegetation cover during the last glacial period as well (Tjallingii et al., 2008). Another notable, important source region during the last glacial period was the region near Patagonia, South America. Provenance studies have repeatedly demonstrated that this region became an important source of dust to the Antarctic Ice Sheet during glacial periods (Basile et al., 1997; Delmonte et al., 2004; Gabrielli et al., 2010; Grousset et al., 1992).

During ice ages when large ice sheets covered large portions of the continents in the Northern Hemisphere, the increase in

frozen ground cover is likely to have inhibited some dust emissions from high latitude sources. At the same time, glacial grinding associated with expanded glaciers also provided an important source of dust to the atmosphere. In fact, inclusion of inferred, glaciogenic dust sources in one model simulation increased LGM emission estimates by 57% and helped to account for massive dust deposition rates observed downwind of sources in North America, Europe, and Asia (see Mahowald et al., 2006a and references therein).

Several modeling studies have demonstrated that the impact of glacial climate on soil moisture, expanded continental shelves, vegetation, and winds resulted in increases in dust emissions and deposition that were comparable to the two- to threefold increases found in observational records at the LGM compared to today (Table 1). However, a closer look at those simulations demonstrates that while these simulations all reproduce glacial–interglacial changes in dust emissions that are similar to those expected from observed changes, the reasons responsible for the changes in dust deposition are very different. Simulated increases in LGM dust source regions range from 35% to 200%. The contribution of enhanced wind strengths over existing source regions to increased glacial dust emissions range from 3% to 65%. Only one of these model simulations has even inferred the impact of glaciogenic sources (Mahowald et al., 2006a). This wide range of differences in model simulations suggest that our ability to constrain future changes in dust source areas and dust emissions in response to anthropogenic climate change remains a challenge.

Atmosphere – The Impact of Dust on the Radiative Budget in the Past, Present, and Future

The overall radiative impacts of dust have been difficult to quantify. Estimating a global impact of dust on the radiative budget is difficult because both the sign and the magnitude of

Table 1 Simulated changes in dust emissions during the Last Glacial Maximum

Study	Simulated changes	Total change in emissions (LGM/Today)	% Change in source area extent	% Contribution to LGM emission increases	
				Winds over current sources	Expanded source areas
Mahowald et al. (1999)	Vegetation + CO ₂	3.0	+200	3	97
Werner et al. (2003)	Vegetation + CO ₂ + shelf	2.2	+270	65	35
Mahowald et al. (2006a)	Vegetation + CO ₂	2.1	+35	36	64
Mahowald et al. (2006a)	Vegetation + CO ₂ + glaciogenic	3.3	+35 + glaciogenic	18	82
Takemura et al. (2009)	Vegetation + shelf	2.4	n/a	60	40

Percent changes in emissions are expressed as percent increase at the LGM relative to today.

the impact of dust particles on the radiative balance depends on the optical properties of dust particles as well as the underlying albedo of clouds or the land surface. Dust can either increase or decrease planetary albedo, or surface reflectivity, depending on both the single scattering albedo of the dust particle as well as the albedo of the underlying surface. Dust can have a cooling effect over optically dark surfaces such as forests and ocean by reflecting incoming solar radiation to space and reducing radiative fluxes at the surface. In contrast, over highly reflective surfaces such as ice sheets, deserts, and snow, dust can increase the absorption of solar radiation and decrease snow surface albedo (e.g., Clarke and Noone, 2007; Wagenbach et al., 1996). For example, the incorporation of dust into surface snow layers can decrease the surface albedo by half (Aoki et al., 2006). To complicate matters further, dust particles may also alter the radiative budget via indirect effects such as providing condensation nuclei for ice cloud formation (e.g., Andreae and Rosenfeld, 2008; Rosenfeld et al., 2001; Su et al., 2008; Yin and Chen, 2007).

Higher atmospheric dust loadings during the last Ice Age are likely to have impacted the planet's radiative budget as well as surface temperatures. Three studies have estimated changes in the impact of glacial dust on radiative forcing during the LGM (Claquin et al., 2003; Mahowald et al., 2006b; Takemura et al., 2009). All three have suggested that the overall global impact of dust ranged from -0.88 to -1.04 W m^{-2} at the top of the atmosphere. Placed in perspective, this change is small relative to local radiative cooling estimated for Northern Hemisphere ice sheets at the LGM (i.e., -20 W m^{-2} ; Hewitt and Mitchell, 1998), but of the same order or magnitude as that estimated for modern radiative forcing associated with all anthropogenic activities (i.e., $+1.6 \text{ W m}^{-2}$; IPCC, 2007). The largest impacts were observed in the tropics in all studies. Claquin et al. (2003) estimated that the negative radiative forcing due to dust reached values of -2.2 to -3.2 W m^{-2} while Mahowald et al. (2006b) saw values as great as -4 W m^{-2} at the top of the atmosphere. Takemura et al. (2009) suggest that the direct radiative impacts of glacial dust were close to zero at the tropopause and only achieve a -0.9 W m^{-2} decrease in the radiative forcing when indirect effects of dust as ice cloud condensation nuclei are included. Although these studies produce different spatial patterns of radiative forcing and for different reasons, all three studies suggest that the radiative feedbacks associated with enhanced atmospheric dust loading were likely to contribute to a cooler climate during the LGM. The globally averaged response of the radiative forcing due to

glacial dust was a reduction in surface temperatures by 0.85°C (Mahowald et al., 2006b).

Sea-Dust as a Fertilizer

In addition to their impact on the global radiative budget, dust particles contain materials such as iron, phosphorus, and silica that are essential to the productivity of marine ecosystems. In many parts of the ocean, the critical concentrations of dissolved iron are very low relative to other necessary nutrients for phytoplankton production. Dust is frequently considered to contain approximately 3.5 wt% of iron on average (Duce, 1986; Duce and Tindale, 1991; Fung et al., 2000; Taylor and McClennan, 1985; Zhu et al., 1997), although this number can vary by region, material type, and particle size (Baker and Jickells, 2006; Muhs et al., 2010b). Nevertheless, additional inputs of iron via atmospheric dust could lead to an increase in phytoplankton activity and growth, and in some cases increased fixation and storage of carbon in the ocean. This hypothesis has been the subject of extensive modeling work, data studies, and multiple large-scale field experiments (de Baar et al., 2005). In fact, the impacts of sprinkling iron on the Southern Ocean as part of one of these experiments was visible from space satellites (Figure 5). Given that atmospheric dust deposition was two to five times greater during glacial periods, Martin (1990) suggested that the effect of iron fertilization from enhanced dust deposition to the oceans during Ice Ages would be large enough to reduce atmospheric carbon dioxide concentrations to their glacial levels. Indeed, modeling and observational studies that have focused on the impact of dust during the last glacial period have found that the feedback of dust upon atmospheric CO₂ is likely to contribute in the range of 10–40 ppm to the glacial–interglacial change in CO₂, with a best estimate of 15 ppm (Kohfeld and Ridgwell, 2009). However, sensitivity studies investigating the impact of aeolian iron inputs on carbon sequestration in the ocean have suggested that even a 50% reduction in aeolian inputs to the ocean would have a limited effect, increasing atmospheric CO₂ by only 14 ppm (Parekh et al., 2006). A fivefold increase in aeolian iron input would decrease atmospheric CO₂ by approximately the same amount (Mahowald et al., 2009). At the same time, dust inputs can have large regional importance to biogeochemical cycling within the ocean that is particularly dependent on intermittent aeolian sources of soluble iron. For example, Crusius et al. (2011) estimate that local contributions

Figure 5 Dust can be a source of nutrients such as silica and iron. In many parts of the ocean, the critical concentrations of dissolved iron are very low relative to other necessary nutrients for phytoplankton production. As a result, we find many parts of the ocean where additional aeolian inputs of iron via dust would lead to an increase in phytoplankton activity and growth (Boyd et al., 2007), and in some cases carbon export (Buesseler et al., 2004; Pollard et al., 2009). Ocean color satellite (SeaWiFS) image of surface ocean chlorophyll concentrations, taken approximately 6 weeks after iron was released in the Southern Ocean. The patch of green affected by the iron is ~ 100 km across. (SeaWiFS data provided by the NASA DAAC/GSFC and copyright of Orbital Imaging Corps and the NASA SeaWiFS project, and processed at CCMS-PML.)

of soluble iron from one glacial flour dust storm event to the Gulf of Alaska was 60–400 tons, comparable in magnitude to annual iron sources from coastal eddies. The impact of this previously unrecognized source of iron deposition from dust, particularly on local primary producers, remains to be determined. These results taken together suggest not only that aeolian inputs have a substantial impact on the ocean carbon cycle, but also that our current knowledge of the sensitivity of the ocean carbon cycle to iron from dust requires further analysis, particularly for understanding regional influences of dust upon marine ecosystems.

Implications for Future Changes in the Dust Cycle

One might also anticipate that future changes in climate attributable to human activities are likely to perturb dust emissions, although the climate-related changes in future atmospheric dust loadings are much less certain. Several previous studies have predicted that dust emissions may decrease by 20–60% from today's levels by 2090 while others suggest that emissions may increase by as much as 200% (Mahowald et al., 2006a; Tegen et al., 2004; Woodward et al., 2005). Analysis of simulations of source areas from seventeen different models shows that they predict increases and decreases of up to 50% in desert area (Mahowald, 2007), emphasizing that our predictions of changes in desert areas (and therefore ultimately dust emissions) are rather uncertain.

Our estimations of the global and regional radiative impacts of dust also contain large uncertainties. The IPCC (2007) has recently provided a best estimate of -0.1 W m^{-2} for the direct radiative effect of anthropogenic dust, with values ranging from -0.3 to $+0.1 \text{ W m}^{-2}$. This range of values appears considerably smaller than estimates for the Third Assessment Report in which values ranged from -0.6 to $+0.4 \text{ W m}^{-2}$ (Houghton et al., 2001). Between the publication of these two reports, new constraints have been placed not only on the estimated magnitude of anthropogenic emissions (dropping the value from 50% to 20% of the global loading), but also on estimates of the optical properties of dust. In fact, when one examines the summed natural and anthropogenic radiative forcing for dust, our newest computed values range from -1.5 to $+0.5 \text{ W m}^{-2}$. This range, although slightly more negative, is not much different from the values published by the Third Assessment Report (-1.3 to $+0.8 \text{ W m}^{-2}$). Regionally, the radiative impact can be two orders of magnitude larger, more than 100 W m^{-2} . Temporal changes in the anthropogenic contribution to desert dust in the atmosphere are equally difficult to quantify, but recent attempts combining observations and modeling suggest that changes in anthropogenic desert dust have reduced the direct radiative forcing at the top of the atmosphere by $-0.14 \pm 0.11 \text{ W m}^{-2}$ over the twentieth century (Mahowald et al., 2010). Nevertheless, our uncertainty about the overall radiative forcing of dust remains large due to the paucity of data sets, uncertainties in the optical properties of mineral aerosols, and our ability to quantify indirect effects.

Estimating the future impact of dust on iron fertilization in the ocean is faced with some of the same uncertainties encountered when estimating the future emissions and radiative impacts of atmospheric dust. For example, modeled estimates of future dust emissions resulting from climate-induced changes in winds and vegetation predict both positive to negative changes (Mahowald et al., 2006a,b; Tegen et al., 2004; Woodward et al., 2005). Understanding the processes controlling the solubility and bioavailability of iron is currently a field of extensive study, and several aspects of the iron cycle are greatly simplified in model experiments. Iron solubility, for example, is normally expressed as a constant 3.5%, whereas measured solubilities of atmospheric iron range from less than 1% to 81% (Baker et al., 2006a,b; Johansen et al., 2000; Schroth et al., 2009; Siefert et al., 1999). Furthermore, anthropogenic emissions of iron from combustion sources tend to increase the solubility. Confounding this impact even further is the impact of climate changes on ocean circulation, which may affect the ability of regions of the ocean to utilize iron (for review see, e.g., Mahowald et al., 2009).

Conclusion

In conclusion, several advances have been made in our understanding of the dust cycle over the past few decades. Our ability to model dust within the Earth system has greatly improved, and our quantification of changes in dust during the last glacial cycle has also led to understandings of some of the first-order controls on dust at a global scale. We have a reasonable understanding of the first-order contribution of iron fertilization of dust to changes in atmospheric CO_2 on glacial–interglacial timescales.

Several challenges remain. Our understanding of the radiative impact of dust today remains uncertain, hindered by uncertainties in our understanding of the optical properties of dust as well as our quantification of emissions and the anthropogenic contribution to the atmosphere dust loading. These uncertainties increase as we attempt to predict what the future changes in dust emissions, atmospheric dust loadings, and dust impacts on global biogeochemical systems are likely to be.

The Active Layer

Meteorological parameters constitute the dominant control over temperature at the ground surface at most locations on Earth. Many of these (e.g., incoming and outgoing radiation, air temperature) follow one or more periodic courses, including daily, annual, and longer (e.g., glacial–interglacial) fluctuations. These fluctuations cause heating and cooling of the ground to depths proportional to the period of fluctuations. In most temperate and cold regions, as well as in areas of high elevation, periodic annual ground temperature transitions

through 0 °C (32 °F) result in seasonal freezing and thawing of the upper ground layer. In areas where the ground remains frozen only during the colder part of the year, this layer is termed ‘seasonally frozen ground.’ In areas underlain by perennially frozen strata (permafrost), the overlying layer subject to seasonal thaw and freezing is called the ‘active layer’ (**Figure 1**). The active layer is of considerable importance in permafrost regions because most geomorphic, hydrological, and biological processes occur in it. Changes in its thickness induced by human action or climatic change can have profound consequences for ecological systems and human infrastructure.

Figure 1 Ground temperature ‘envelope’ in a typical contemporary permafrost region (solid lines). Higher temperatures are to the right and lower to the left; 0 °C is represented by a vertical dashed line. The thermal profile in summer forms the right-hand component of the ‘trumpet curve’; its intersection with the 0 °C line defines the thickness of the active layer. The depth of zero annual amplitude is the level below which no significant season temperature fluctuations are registered. The dashed trumpet curve depicts changes in the thermal profile introduced by a simple increase in the mean annual temperature at the ground surface. Prominent among these changes are thickening of the active layer and a decrease in the thickness of permafrost.

Definition

The term ‘active layer’ was first proposed by Sumgin, who defined it as “the layer of seasonal thaw in permafrost areas” (Sumgin, 1927, p. 56). The term was later introduced to English scientific literature by Muller (1947). The International Permafrost Association’s *Multi-Language Glossary of Permafrost and Related Ground Ice Terms* (van Everdingen, 1998) defines active layer as “the layer of ground that is subject to annual thawing and freezing in areas underlain by permafrost.” Conceptually, the definition of the active layer is straightforward, although its precise meaning is a subject of some scientific debate. The main source of contention is the meaning of the term ‘frozen ground,’ which can indicate either solidification by ice or cooling below 0 °C (Burn, 1998). Although the distinction between these meanings seems minor, it can result in major differences in describing the overall permafrost system. For example, the ice-nucleation temperature in soils can be depressed due to salinity, capillary effects, and pressure, causing ground to remain unfrozen at temperatures below 0 °C. Because permafrost is defined as ground that remains below 0 °C for 2 or more consecutive years, the bottom portion of the active layer defined on the basis of phase changes of water can be considered as a part of the permafrost layer. Alternatively, the temperature-based definition of the active layer clearly separates it from permafrost. Sumgin’s (1927) original definition did not

differentiate between these two meanings. In contrast, Muller (1947) defined the active layer as a “layer of ground above permafrost which thaws in summer and freezes again in winter” (Muller, 1947 p. 213), indicating that the base of the active layer occurs at the depth of maximum seasonal penetration of the 0 °C isotherm into the ground. Many permafrost researchers (e.g., Burn, 1998; Nelson and Hinkel, 2003) prefer the definition based entirely on thermal criteria, without regard to material composition or properties, as it clearly differentiates between the components of the permafrost system and is more easily applicable to field and modeling studies.

The active layer is the only part of the permafrost system that experiences substantial changes in its physical properties during each annual cycle. These changes involve variations of ice/liquid water content, thermal conductivity, density, and mechanical properties, all of which are of critical importance for many natural phenomena and processes. Most geomorphic, biological, and hydrological activities in permafrost-affected soils are confined to the layer of seasonal thaw.

Physical Processes

With the exception of locations where no appreciable moisture is present, seasonal thawing and freezing of the ground is a complicated physical process involving temperature change, phase transition, moisture migration, ground heave and subsidence, and changes in the mechanical, chemical, and thermal properties of the ground. Appreciation of several physical processes is essential for understanding the dynamics of the layer.

Propagation of Thawing and Freezing Fronts

The process of seasonal thawing is initiated when sufficient heat arrives at the ground surface (i.e., when snowmelt is complete) and continues until the end of the warm season, with the onset of refreezing. Although heat transfer occurs primarily by conduction at most locations, nonconductive processes (e.g., coupled heat and moisture flow) can be significant (Hinkel et al., 1997; Outcalt et al., 1990). Convective heat transfer by infiltration of precipitation can also have a significant effect (Hinkel et al., 2001). During autumn freezeback, the active layer cools rapidly to 0 °C and becomes isothermal. Subsequent cooling initiates propagation of the freezing front from the surface downward. One of the main features distinguishing many permafrost environments from the seasonally frozen ground of nonpermafrost regions is the existence of bodies of segregated ice in positions corresponding to the long-term base of the active layer. The frozen ground acts as a heat sink and, depending on the local situation, progressive freezing occurs simultaneously from the surface downward and upward from the base of the active layer (Figure 2). This situation, termed ‘two-sided freezing,’ results in layers of segregated ice just below the surface and at the base of the active layer. Freezing from below is widespread in areas with permafrost temperatures below –5 °C, where it is usually precedes freezing from the surface (Shur, 1988). Two-sided freezing is a highly significant phenomenon because it controls many important physical and geomorphic processes in permafrost environments (Mackay, 1981).

Figure 2 Active-layer temperature profile during freezing as observed on 20 September 2002 in Barrow, Alaska. The mean annual permafrost temperature at the base of the active layer is approximately -8°C . Note the two-sided freezing, indicated by freezing fronts moving downward from the surface and upward from the permafrost table. The maximum thaw depth of 37 cm was reached on 28 August, followed by progressive freezing from the bottom. Freezing from the surface began on 15 September. The position of freezing fronts stabilized at approximately the depths shown on **Figure 3** until 29 October, due to release of the latent heat associated with moisture migration and ice formation at the freezing fronts. Note the isothermal zone with temperatures close to 0°C . Once the isothermal zone became desiccated, the progression of the freezing fronts was very rapid and the entire active layer was frozen to temperatures below -1°C by 3 November.

Zero-Curtain Effect

The permafrost table just below the active layer is relatively impermeable, although the upper layers of permafrost can contain appreciable amounts of unfrozen water (Romanovsky and Osterkamp, 2000), and migration of moisture through the active-layer/permafrost boundary has been documented (Mackay, 1983). Complemented by low evaporation, a characteristic feature of cold regions, this results in accumulation of substantial amounts of water within the active layer, especially in areas of level terrain such as the Arctic coastal plain of northern Alaska. The presence of water significantly modifies heat propagation within the active layer due to latent heat effects associated with transitions between the liquid and solid phases. During freezing, large quantities of heat are released by ice nucleation, whereas during thaw, large amounts of heat are absorbed by the melting of ice. Because release or absorption of latent heat does not result in temperature change, the active layer can remain near 0°C for relatively long periods of time while the water within it

Figure 3 Temperature time series within the isothermal zone of **Figure 2**, at the depth of 25 cm. Note the prolonged period (48 days, 10 September until 28 October) when temperature remained within 0.1°C of the freezing point (zero-curtain effect).

undergoes phase change (**Figure 3**). Sumgin (1927) called this phenomenon the 'zero-curtain effect.' Outcalt et al. (1990) demonstrated that vapor transport and internal distillation can play an important role in forming and maintaining the zero-curtain effect, which can also occur in freezing soils outside permafrost regions. Although it has been defined in various ways, the term 'zero curtain' should be regarded only as an effect; units of measurement should not be assigned to it (Outcalt et al., 1990).

Ice Segregation

If unfrozen water is present in the ground, the process of active-layer freezing is accompanied by water migration toward the freezing front, due to gradients of potential (free energy) between frozen and unfrozen water. This process is sometimes referred to as 'cryosuction.' The process of water migration and subsequent freezing is known as 'ice segregation.' The resulting segregation ice is usually arranged in horizontal layers or lenses oriented perpendicular to the propagation of the freezing fronts, with desiccated layers between. If vertical cracks occur, however, the ice lenses can form within them as the freezing front proceeds, resulting in vertical ice layers. Although ice segregation is common within the seasonally frozen layer of nonpermafrost regions, it is more pronounced under slow upward freezing from the base of the active layer in areas underlain by permafrost. In this case, water migration toward a freezing front coincides with gravitational migration, resulting in a relatively thick layer of ice accumulation at the bottom of the active layer. The amount of segregated ice depends on freezing intensity, prewinter moisture content, the existence of external supplies of water, and soil texture. The latter parameter is a major control over ice segregation, which occurs predominantly in medium-textured soils (silt), due to capillarity. The low permeability of clay-rich sediments limits water movement through the soil and inhibits ice segregation. Although sands and other coarse-grained materials do not contain segregation ice in areas of seasonal freezing (due to their high permeability), in permafrost areas, it can occur as a result of favorable

freezing conditions over long periods of time. Peat is not particularly susceptible to ice segregation, although its unusual thermal properties may enhance the process in underlying fine-grained soils. The vertical distribution of ice lenses is controlled by the composition and distribution of sediments, cracks, and voids within the active layer, as well as by the geometry of the freezing process.

Frost Heave and Thaw Subsidence

Ice segregation and volumetric expansion of water during freezing can result in heaving of the ground surface, a process referred to as 'frost heave.' Subsequent melting of these ice layers in spring causes thaw subsidence (settlement) of the ground surface. Because ice segregation depends on factors that vary spatially and temporarily, frost heave and thaw subsidence are not uniform, and can vary from place to place and from year to year. Frost heave and thaw subsidence can displace buildings, roads, airport runways, railways, pipelines, drainage systems, and other structures (Figure 4). These processes are also of great importance in the development of many of the periglacial geomorphic features of cold regions, including patterned ground, palsas, pingos, seasonal frost mounds, and a wide array of mass-movement features. Techniques for measuring the magnitude of frost heave and thaw subsidence in permafrost regions were reviewed extensively by Tait et al. (2005). Global positioning systems technology appears to have considerable potential for monitoring these processes (Little et al., 2003).

Cryoturbation

Periodic freezing and thawing of soils and the associated processes of ice segregation, frost heave, and thaw subsidence all affect soil structure. Changes in soil structure induced by these processes include enlargement of pores and voids, loosening, aggregation, and sorting of soil particles. The collective term used to describe all soil movements due to frost action is 'cryoturbation' (van Everdingen, 1998). This term is also used to describe irregular structures formed in earth material by frost-action processes, characterized by folded, broken, and dislocated beds and lenses of unconsolidated deposits, including organic horizons and even bedrock.

Active-Layer Thickness

Factors Influencing Active-Layer Thickness

The impacts of annual thaw depend, to a very large degree, on the depth to which it penetrates. The term 'active-layer thickness' (ALT) refers to the thickness of the thawed layer (measured normal to the ground surface) that is reached at the end of the warm season (van Everdingen, 1998). This is distinct from the term 'thaw depth,' which refers to the thickness of the thawed layer at any time during its development in summer. In other words, thaw depth is essentially an instantaneous value that is always less than or equal to the thickness of the fully developed active layer (Nelson and Hinkel, 2003).

Factors influencing the annual thickness of the active layer and its spatial and temporal distribution include

Figure 4 Bicycle trail affected by differential thaw settlement near Fairbanks, Alaska. An increase in ALT, induced by increased absorption of solar radiation by the dark paving material, has penetrated into ice-rich permafrost, causing thaw consolidation and subsidence at the surface. Much of the permafrost near Fairbanks is very close to 0 °C and relatively small disturbances render it susceptible to thaw. Although this example was not induced by climatic warming, it illustrates (a) the type of disturbance that could result under a sustained increase of air temperature and (b) the great geographic variability in thaw settlement possible over even short distances.

1. mean annual surface temperature,
2. the amplitude of the annual temperature cycle at the ground surface, which reflects the degree of climatic continentality,
3. the composition and thermal properties of the subsurface material, and
4. the ground moisture regime.

The 'Stefan Solution,' a simple analytic tool for estimating the depth of thaw, illustrates the roles of these parameters. The Stefan estimate of the depth to which thaw penetrates is given by

$$Z_t = [(2\lambda_t s T t)/(\rho w L)]^{1/2} \quad [1]$$

where Z_t is thaw depth (m); λ_t the substrate's thermal conductivity in the thawed state ($\text{J s}^{-1} \text{m}^{-1} \text{°C}$); T , the mean temperature of the thawing season (°C); t , the length of the thawing season (days); s a scaling factor (s d^{-1}); ρ , soil density

(kg m^{-3}); w , water content (expressed in dimensionless form on a volumetric basis); and L is the volumetric latent heat of fusion (J kg^{-1}). The quantity (Tt), known as the 'thawing index,' is also referred to as 'cumulative degree-days of thawing' (DDT). The thawing index is a time–temperature integral usually computed as the sum of mean daily temperatures above 0°C over the course of the thaw season.

Owing to its neglect of heat capacity and to several other simplifying assumptions, the Stefan Solution usually overestimates the depth of thaw. Numerous improvements to this simple analytic expression (reviewed in Andersland and Ladanyi, 2004) have been developed, but the structure of [1] illustrates clearly the most important factors affecting the depth of thaw. The proportionality between ALT and the square root of the thawing index is demonstrated in Figure 5. The Stefan equation and its variants can also be used to predict the depth to which frost penetrates in regions of seasonally frozen ground. Estimates of thermal conductivity based on a given soil's texture, density, and moisture content are widely available as tables or nomograms (e.g., Andersland and Ladanyi, 2004). More sophisticated numerical models of soil thermal evolution (e.g., Goodrich, 1982, and the many variants of his model) are preferred over analytic expressions when data sufficient to parameterize such models are available.

The composition and texture of subsurface materials determine their thermal conductivity and heat capacity which, in turn, influence the rate and depth of heat propagation into the ground. Fine-grained soils generally have smaller values of thermal conductivity than coarser sediments do. Under similar

conditions, the thickness of the active layer will be greatest in coarse-grained sediments such as sands and gravels. The presence of ice and water close to their transition temperature has a major effect on the thermal properties of soils within the active layer. When unfrozen water changes to ice, its conductivity increases by approximately four times so that frozen soils have higher thermal conductivity than unfrozen soils do. Owing to this effect, known as the 'thermal offset,' under equal absolute values of temperature gradient, the active layer loses more heat in winter than it gains through the summer, and hence permafrost can exist at locations where the mean annual surface temperature is slightly positive. The thermal offset is especially pronounced in natural peat. The heat capacity of unfrozen water is approximately double that of ice, which leads to higher heat capacity in unfrozen soil. Although this effect tends to be smaller than variations of thermal conductivity, significant changes of heat capacity can be associated with the period when phase changes occur. Changes of heat storage in the soil include a large latent heat component over the range of phase-change temperatures, leading to significant increases of heat capacity.

Soil moisture affects the thickness of active layer in two ways: through changes in the thermal properties of soil and through the amount of phase transition, which generally has a more pronounced effect. In general, the greater the amount of water in the ground the greater the amount of heat consumed for phase transition and the thinner the active layer. In some situations, however, this effect can be offset by the increased thermal conductivity of wet soils. The volume fraction of ice and water depend on temperature and specific site conditions.

It should be noted that increase in precipitation can sufficiently alter the ground thermal regime and promote increase in the ALT, even during periods of climatic cooling. For example, marked increases in the ALT and upper permafrost temperatures occurred in the central Lena River basin, Russia in association with abrupt increases in soil moisture following an extremely wet summer of 2005 (Iijima et al., 2010). Summer precipitations influence the active layer in two ways: (1) through increase in thermal conductivity of soils as discussed earlier and (2) through convective heat transfer associated with the percolation of relatively warm meteoric water through the thawed portion of the soil column (e.g., Hinkel and Outcalt, 1994).

Geographic Patterns and Variability of the Active Layer

Zonal trends in ALT are discernable, if similar soils and surface cover are considered at all sample locations. ALT decreases poleward and increases in continental areas because mean annual temperature at the ground surface and its annual amplitude are arranged across the surface of the Earth in broad geographic zones. At local and regional scales, however, ALT is highly variable over space. Variations of subsurface properties, soil moisture, and snow and vegetation cover modify the zonal pattern radically, resulting in a high degree of geographic variability. Topography also plays an important role in determining ALT because it is an important determinant of the amount of heat received by the ground surface, it affects the distribution of snow and vegetation, and it influences the surface and subsurface moisture regimes. The concept of 'topoclimate' (Geiger, 1969) is, therefore, a very important consideration in studies of ALT.

Figure 5 Ten-year record of ALT, plotted against $\sqrt{\text{DDT}}$ at two 1 km^2 CALM sampling locations in northern Alaska. The West Dock location is on the Arctic Coastal Plain physiographic region, an area of low relief and abundant ponds and lakes. Happy Valley is in the Arctic Foothills, with substantial relief and large variations in vegetation and snow cover. Despite large differences in the scale of maximum variability of ALT at these locations (Nelson et al., 1999), the average ALT value from 121 sample points at each location conforms to the structure of the Stefan relation (eqn [1]). Mean ALT values at both locations closely track seasonal air temperature.

The spatial variability of soil and ground moisture, amplified by cryoturbation and ice-segregation processes, can also result in great variability of ALT over small lateral distances. Interannual variations, however, indicate a strong dependence on air temperature (Figure 5), which may be subject to change under sustained climatic change. Estimating and monitoring changes in the thickness of the active layer, a major component of the Arctic terrestrial ecosystem, is of primary importance for most practical applications in engineering and ecology. An international active-layer monitoring program, currently comprising about 200 sites, operates under the name 'Circumpolar Active Layer Monitoring' (CALM) network (Nelson et al., 2008; Shiklomanov et al., 2010).

The Transition Zone

Numerous studies have demonstrated that the genesis and properties of the uppermost permafrost differ from those of the underlying permafrost. The uppermost layer is subject to episodic thaw at subdecadal to multicentennial scales and is referred to as the 'transition zone' (Shur et al., 2005). Its lower bound is the long-term permafrost table and coincides with the top of primary ice wedges. The transition zone is important for permafrost stability and serves as a buffer between the active layer and ice-rich permafrost, especially permafrost containing massive ice. The zone can aggrade and change properties over time through ice segregation (Mackay, 1983) and by infiltration of meteoric water or meltwater from ground ice in the overlying active layer, with subsequent refreezing (Hinkel et al., 2001). The existence of the transition zone explains the fact that wedge ice and other massive ice formations are frequently located well below the active layer (Shur, 1975). Ice veins or rejuvenated ice wedges (secondary or tertiary growth stages) have been observed extending from primary ice wedges upward into the transition zone, indicating reactivation of ice-wedge growth (Lewkowicz, 1994).

The transition zone is ice-rich, with the ice content often much greater than in the permafrost immediately beneath it (e.g., Kanevskiy, 2003; Kokelj and Burn, 2003; Shur, 1988). Ice occurs as segregation lenses, ice veins, and contemporary ice wedges (Lewkowicz, 1994; Shur, 1988). In the continuous permafrost zone, the cryogenic structure of this layer differs significantly from that of the underlying permafrost. In Russian permafrost literature, the characteristic net-like cryogenic structure found in the transition zone is known as 'atactic'; Murton and French (1994) refer to it as 'suspended.' Owing to latent heat effects, the ice-rich transition zone resists thaw and tends to promote thermal stability at greater depths (Shur, 1975; Smith, 1988). Although the transition zone is enriched with ice relative to the active layer, the upper region contains less ice than underlying regions because it thaws more frequently. The uppermost part of the transition zone is referred to as the 'transient layer.' Deep thaw is largely driven by changes in the surface energy equation due to interannual variations and climatic fluctuations, and occurs at the subdecadal to multicentennial scale. During most warm years, the transient layer protects the underlying ice-rich materials from thaw. Deeper in the transition zone, thaw is less frequent and occurs in response to climate change or a major disturbance (Figure 6).

Figure 6 Schematic diagram of a three-layer model of the permafrost-active layer system: (1) active layer (seasonal freezing and thawing), (2) transient layer with high and quasiuniform ice content and freezing/thawing at decadal to century scales, and (3) long-term permafrost (freezing and thawing at century to millennial scales), with spatially inhomogeneous ice content. Shur YI (1988) The upper horizon of permafrost soils. In: Senneset K (ed.) *Proceedings of the Fifth International Conference on Permafrost*, pp. 867–871. Trondheim, Norway: Tapir.

The Active Layer and Climate Change

Roles in Climate-Change Science

Because most geomorphic, biological, and hydrological processes in permafrost regions are restricted to the active layer, long-term changes in its thickness can have important consequences for natural and human systems. As with permafrost (US Arctic Research Commission, 2003), the active layer assumes three important roles in climate-change science: translator, facilitator, and record keeper.

Translator

The active layer translates climatic change to natural and human systems because increases in ALT can lead to thaw settlement, development of thermokarst terrain, and destabilization of human infrastructure at the surface (Nelson et al., 2002). Depending on subsurface conditions, thaw settlement induced by melting ground ice can have very disparate hydrological changes at the surface. Jorgenson et al. (2001) described widespread ecological changes in central Alaska, in which birch forests established on ice-rich 'uplands' have been transformed into extensive wetlands by thaw settlement. In western Alaska, Smith et al. (2005) found that thaw of ice-rich permafrost established subsurface drainage ways, ultimately leading to the draining of large lakes and drying at the surface.

Facilitator

Widespread increases in ALT induced by climatic warming have the potential to facilitate and amplify that warming. Large quantities of organic carbon are known to be stored in near-surface layers of permafrost. A widespread increase in ALT could

mobilize much of this carbon, releasing it to the atmosphere in the form of methane and carbon dioxide and leading to amplified climatic warming. Uncertainties about the amount of carbon sequestered in high-latitude regions, details of hydrological responses to thaw, and the evolution of vegetation preclude precise estimation of the contribution of thawing permafrost to climate change at present (Hobbie et al., 2000; Stokstad, 2004; Sturm et al., 2001).

Record keeper

Permafrost contains a great deal of proxy information about past climatic changes. Cryostratigraphic techniques (French, 1998; Murton, 2001), used in concert with isotopic analysis, provide information about increases in ALT that occurred millennia ago. Such evidence includes truncated ice wedges, ice- and sediment-wedge casts, and thaw unconformities.

Simulation studies indicate that widespread increases in ALT will occur in conjunction with climatic warming (Anisimov et al., 1997; Nelson et al., 2001). One of the most difficult challenges facing permafrost scientists evaluating the impacts of climate change is to differentiate between climate-induced and anthropogenic effects (Hinzman et al., 2005; Nelson, 2003).

Observed ALT Trends

Thaw-depth observations in permafrost regions indicate substantial interannual fluctuations in ALT, primarily in response to variations in summer air temperature (Popova and Shmakin, 2009; Smith et al., 2009). Decadal trends in ALT vary by region. A progressive increase in ALT has been observed in some Nordic countries (Åkerman and Johansson, 2008; Callaghan et al., 2010). However, the increased thaw propagation has stopped during the past 3 (2007–2010) years, as ALT has been more or less stable, mainly due to dry summer conditions (Christiansen et al., 2010). Observations on Svalbard and Greenland show increased ALT since the late 1990s, although the increase is not spatially and temporarily uniform (Christiansen et al., 2010).

Significant permafrost degradation has been reported in the Russian European North. As a result of recent climatic warming, ALT has increased significantly (Mazhitova, 2008; Mazhitova et al., 2008) and permafrost patches that were 10–15 m thick have thawed completely in the Vorkuta area (Oberman, 2007). Permafrost degradation is also evident in the discontinuous permafrost zone of West Siberia (Romanovsky et al., 2010). However, areas of West Siberia underlain by continuous permafrost do not show pronounced ALT trends (Vasiliev et al., 2008). Increased ALT since the mid-1990s has been observed in East Siberia (Fyodorov-Davydov et al., 2008) and Chukotka (Zamolodchikov, 2008). The frequently reported long-term permafrost thawing in Eastern Siberia, Russia, near the city of Yakutsk, is related directly to natural or anthropogenic disturbances such as forest fires, agriculture, and infrastructure development (Federov, 1996; Federov and Konstantinov, 2008) and does not correlate with climate (Romanovsky et al., 2010).

The permafrost areas of Central Asia have experienced a general increase in ALT. On the Qinghai–Tibet Plateau, an increase of 7.5 cm year⁻¹ was reported from 1995 to 2007 in response to an increase in air temperature (Wu and Zhang, 2010). Rates of ALT increase up to 40 cm year⁻¹ over the past

decade were observed at some Mongolian locations with warm permafrost.

ALT trends are different for North American sites. There, a progressive increase of ALT is evident only at sites in the Alaskan Interior, where in 2007, the maximum ALT for the 18-year observation period occurred (Viereck et al., 2008). On the Alaskan North Slope, ALT is relatively stable, lacking pronounced trends over the 1995–2008 period (Streletskiy et al., 2008). Similar results are reported from the Western Canadian Arctic. Smith et al. (2009) found that there was no definite trend in ALT over the last 15 years in the Mackenzie Valley. At several locations, the active layer has thinned after 1998. Results from long-term monitoring in the northern portion of the Mackenzie Valley indicate that there was an increase of 8 cm in thaw depth between 1983 and 2008; but the maximum was in 1998, and since then, thaw depths have generally been shallower (Burn and Kokelj, 2009). In the eastern portion of the Canadian Arctic, ALT has increased since the mid-1990s, with the largest increase occurring in bedrock in the discontinuous permafrost zone (Smith et al., 2010).

Thaw penetration into an ice-rich layer at the base of the active layer is accompanied by loss of volume (thaw consolidation), manifested as subsidence at the ground surface. Results from monitoring of the position of the ground surface at representative locations on the North Slope of Alaska indicate that up to 11 cm in subsidence had occurred over the 2001–2008 period (Streletskiy et al., 2008). Similar results have been obtained from the Russian European North, where increases in ALT caused subsidence of 20 cm over the 1998–2008 period (Mazhitova and Kaverin, 2007). A subsidence of 1–4 cm/decade was estimated by Liu et al. (2010), who have used interferometric synthetic aperture radar to measure surface deformation from 1992 to 2000 over permafrost on the North Slope of Alaska.

Concluding Comments

The active layer is an important component of the permafrost system. Its thermal behavior and thickness constitute an important influence on geomorphic and hydrologic processes, ecosystems, and human activities. Although numerical simulation studies indicate that widespread thickening of the active layer could occur in conjunction with global warming, the existing record of ALT shows diverse regional patterns. Numerous feedback mechanisms involving vegetation succession (Sturm et al., 2001) and hydrological changes (Smith et al., 2005) could act to limit the magnitude of future increases in ALT, even under sustained climatic warming. The monitoring programs implemented by the International Permafrost Association are critical for assessing the evolution of permafrost and the active layer.

This article is a revision of the previous edition article by J. Vandenberghe, volume 3, pp. 2147–2153, © 2007, Elsevier B.V.

Introduction

'Cryoturbation' is a term widely applied to sedimentary deformations that develop under periglacial conditions (Edelman et al., 1936). Its use, however, should be limited to nonsorted deformation features of cryogenic origin, that is, genetically caused by direct or indirect freezing or thawing action (Vandenberghe, 1988). From a descriptive standpoint, cryoturbations are characterized by fluidized structures with smooth boundaries and laminations that point to dominantly liquid or plastic deformation. They generally occur beneath low-angle surfaces and show little or no surface morphological expression. When the genesis of the deformation structure is uncertain, the use of a purely descriptive term ('involution') is recommended.

The great variability of cryoturbation types indicates the wide range of processes involved. Understanding the different cryogenic processes that have produced them is important because the processes are often bound to specific environments and climates. In turn, it is often possible to infer the climatic and environmental conditions from specific cryoturbation types at the time and place where they developed. Therefore, a descriptive classification is presented first, followed by a discussion of the origins of the different types of cryoturbations and, finally, their paleoclimatic significance.

Classification of Cryoturbations

A classification that assigns the wide range of cryoturbation structures to six morphological types has been proposed by Vandenberghe (1988). The deformations are classified according to their diagnostic sedimentary architecture, comprising symmetry and amplitude–wavelength ratio of the folds, and frequency and patterns of occurrence. Because this classification has proved its general applicability during the last two decades, it may be retained with some slight adaptations (Figure 1):

• Type 1 Cryoturbations

Undulations or individual folds of relatively small amplitude (in the range of decimeters) and large wavelength (in the range of a few meters).

• Type 2 Cryoturbations

Closely spaced series of repetitive, generally regular, symmetrical, intensely folded forms. Most reach a common depth and, in horizontal plan view, occur in polygonal patterns over large areas (Figure 2). Downward-extending parts may be flat bottomed. Amplitudes are mostly between 0.5 and 2 m (or occasionally much more). The volume of upward- and downward-extending parts must of course be equal, but the

width–depth ratios of upward- and downward-extending parts, may differ (Figure 1). The width–depth ratios and the amplitude may differ according to the lithological (and thus physical) properties and the relative thickness of the sediment layers taking part in rising or sinking movements.

• Type 3 Cryoturbations

Identical forms and patterns as in type 2, but of distinctly smaller dimensions (drops in the range of centimeters to pockets of a few decimeters; Figure 3).

• Type 4 Cryoturbations

Symmetrical forms, as in types 2 and 3, with different amplitudes; however, they do not occur in series but, rather, as individual forms. The pocket form is the most common one, in contrast to individual dome forms (Figure 4).

• Type 5 Cryoturbations

Apparently similar to type 2, but the lower sediment has risen along platy 'dykes' in contrast to type 2, where the uprising sediments form structures shaped like 'diapirs' or cauliflower flowers (Figure 5). In turn, the upper sediment of type 5 has subsided 'sack-wise,' while in types 2–3, it has subsided along platy 'dykes' (Kasse, 1993; Figure 6).

• Type 6 Cryoturbations

Irregular structures of all dimensions and degrees of contortion.

The Origin of Cryoturbations

Periglacial Loading

Loading is a process often invoked to explain involutions of both cryogenic and noncryogenic origin. In general terms, sediments with relatively high density may sink down into underlying, lighter sediments, while the latter sediments may rise into the upper, heavier ones. This process takes place purely under gravitational forces, without any lateral heterogeneity or force being required. Apart from this 'reversed vertical density gradient,' the intergranular contacts must be released in the lower sediments, leading to liquefaction. This can occur only in saturated soils with high void ratios because the frictional strength of most unconsolidated sediments is too high for plastic deformation (Vandenberghe and Van den Broek, 1982). In flat areas, such prerequisites necessitate an (non-lateral) excess water supply in poorly drained conditions.

The two requirements of general validity (reversed density gradient and liquefaction of the lower layer) are only rarely met in natural conditions. Cryoturbations of type 2 are independent of lithology and vertical sediment successions, and mostly show no original reversed density gradient. However, the existence of

Figure 1 Types of cryoturbation structures, as modified from the classification of [Vandenberghe \(1988\)](#). p.t., permafrost table.

permafrost may create the required conditions ([Vandenberghe, 1988](#); [Vandenberghe and Van den Broek, 1982](#)). The upper part of the permafrost is often the focus of ice segregation and is therefore enriched in ice lenses, which results in a general decrease of the density of these sediments in comparison with the overlying (water-saturated) layer (first requirement). In addition, thaw of this ice-rich upper layer of permafrost can induce liquefaction (second requirement). This type of loading thus operates only in the described specific conditions and is termed 'periglacial loading' (according to [Gullentops and Paulissen, 1978](#)). It explains the type 2 involutions.

A crucial point is the maintenance of nondrained conditions during thaw of near-surface permafrost ([Van Vliet-Lanoë, 1991](#)). Moist, low-lying and flat areas without lateral drainage and underlain by fine-grained sediments (with low permeability) are most favorable for periglacial loading. The independence of the vertical lithological succession is illustrated by the fact that fine-grained sediments (e.g., silt) may sometimes sink down into coarser-grained sediments (e.g., sands or gravels), but the opposite case occurs with the same frequency. The deformations may even develop in lithologically homogeneous sediments ([Vandenberghe, 1988](#)).

The presence of an impervious layer at the time of loading is indicated by the flat-bottomed appearance of the downsinking parts ([Vandenberghe and Van den Broek, 1982](#)) and their common depth over large areas, although their amplitude may vary ([Kasse, 1999](#)). In the absence of lithological discontinuities, there is no other explanation for such an impervious horizon than the top of a frozen soil. Furthermore, the existence of permafrost at the time of loading is occasionally demonstrated by the occurrence of the top of ice-wedge

Figure 2 Type 2 cryoturbations caused by loading processes above degrading permafrost; the amplitude of involutions is ca. 1.60 m. Weichselian sands penetrate down into the underlying and presently compact Lower Pleistocene clays (Meerle, Belgium).

Figure 3 Type 3 cryoturbations caused by loading; the amplitude of the involutions is 30–40 cm. Slightly humic loams penetrate in underlying sands and gravely sands (Weichselian deposits, Nochten, eastern Germany; cf. [Kasse et al., 2003](#)).

pseudomorphs at the same level as the base of cryoturbations ([Vandenberghe, 1983a](#)). The position of that level determines the maximum amplitude of the periglacial loading structures.

There is a striking similarity between cryoturbated three-dimensional (3D) structures and those resulting from loading experiments in the laboratory, including primary reversed density gradients above an impervious horizon ([Anketell et al., 1970](#); [Dzulinski, 1966](#); [Harris et al., 2000](#); [Talbot and Jackson,](#)

Figure 4 Type 4 cryoturbation due to a process of local loading; the amplitude is between 30 and 40 cm (Weichselian Late Pleniglacial; Weelde, northern Belgium).

1987). Although such a ‘similarity’ does not prove a common origin, it does show that it is possible. Loading processes in unconsolidated sediments, as a result of supersaturation, are not always of periglacial origin, even when showing a primary normal density gradient. Such conditions may occur whenever there is an impervious horizon with a local, bowl-shaped topography that creates supersaturation. Examples include Holocene podzolic soils developed in sands, where the impervious layer is formed by the iron-stained and humic illuviation horizon of the soil (Kasse, 1999; Schwan, 1990).

Some involutions have a more limited areal extent (type 3) or even a single occurrence (type 4), and a smaller amplitude (both types 3 and 4). Otherwise, their 3D-architecture (including occasional flat bottoms) is very similar to that of type 2 and, by analogy, also suggests an origin by loading. Their characteristic amplitude and areal extent, however, point to a shallow deformation layer, which may be interpreted as the (seasonally) thawed soil at the time of loading and not the degrading upper layer of permafrost. Oversaturation and liquefaction may be induced by more local conditions of lateral water supply (determined by lithology and topography) instead of the presence of ice lenses in the upper permafrost layer for type 2 cryoturbations. Type 3 cryoturbations often form in topographic depressions that functioned previously

Figure 5 Type 5 cryoturbation formed by injection due to cryohydrostatic pressure. (Weichselian loesses, Maastricht-Belvédère, The Netherlands; Vandenberghe, 1992; Vandenberghe et al., 1987). Height of photograph is 100 cm.

as pools in which low-permeability silts and clays were deposited. Lateral water flow in sands toward the center of the depression may be confined between the overlying fine-grained sediments of low permeability and a lower impervious layer that is represented by the frozen subsoil. This may result in a similar supersaturation and reversed density gradient as in the situation where type 2 deformations originated. Thus, it is not surprising that identical 3D structures develop, although with smaller dimensions.

The amplitude of cryoturbations may vary over a relatively short distance and thus shows a gradual transition from type 2 to type 3 (Kasse, 1999). This may be due to different thicknesses of the oversaturated layer arising from local variations in topography, vegetation, or lithology. This proves that type 3 cryoturbations may occur above permafrost, but they may also be associated with the thaw of a seasonally frozen layer.

Cryohydrostatic Flow

Processes similar to those described earlier for type 3 and 4 cryoturbations may cause sufficiently high pore pressures, resulting not only in fluidization of the sediments but also in injection. Considerable amounts of water may be supplied laterally and trapped between impervious parts of the soil, for example, between the permafrost table below and the downward freezing layer above. Owing to the resulting increased pore water pressure, the unfrozen and fluidized sediment-water mixture may be expelled by hydrostatic pressure into places of lesser resistance. As this process is limited to periglacial conditions, the term ‘cryohydrostatic’ is used (Vandenberghe, 1988). Frost and desiccation cracks may function as zones of obvious soil weakness, and hence polygonal networks of upward-displaced sediment may develop, leading to type 5a cryoturbations (Figure 5). Generally, the original crack is completely destroyed by the intrusion. The deformation is mostly restricted to the surroundings of the crack, which contrasts with the approximately equally alternating up-doming and downsinking structures of type 2 cryoturbations.

The process of upward injection of sediment into a pre-existing frost-crack polygon produces the 3D sedimentary structures shown in Figure 6. In the horizontal section at the

Figure 6 Horizontal, vertical, and 3D diagrams illustrating the different sedimentary structures formed by the mechanisms of loading and cryo(hydro)static pressure. Reproduced from Vandenberghe J (1992) Cryoturbations: A sediment structural analysis. *Permafrost and Periglacial Processes* 3: 343–352, with permission from Wiley & Sons.

top of the structures, a polygonal pattern appears, with a linear network consisting of the lower, intruded material, whereas the space in the core of the cells is composed of the upper sediment; this is in contrast to type 2 and 3 involutions. The 3D patterns therefore make it easy to distinguish these cryoturbation mechanisms from each other (Figure 6; Vandenberghe, 1992). Different frost susceptibility of the soil in a vertical profile (Van Vliet-Lanoë, 1991) is not necessary to create type 5 cryoturbations because identical structures may occur in homogeneous sediments and in layered sediments with different lithologies.

Cryohydrostatic injection may occur along narrow fissures and also as wider intrusions. In the vertical section, the latter resemble loading structures (type 5b in Figure 1). Again, the difference is that here a preexisting polygonal crack pattern is present along which the lower, liquefied sediment moves upward. A polygonal pattern of broad standing plates develops, whereas the original crack forms are generally lost (Kasse, 1993). Many transitional forms may occur between 'fissure injections' and 'intrusions.'

As in type 2 cryoturbations, the generation of sufficient pressure in the liquefied sediment is necessary to overcome the overburden pressure. Therefore, an impervious horizon is required below the unfrozen material, for example, a deeply frozen layer or the permafrost table.

Cryostatic Heave

In contrast to the fluid state (of unfrozen sediment) in gravitational loading and cryohydrostatic flow, plastic deformation

(in freezing sediment) is involved in the process of cryostatic heave. Cryostatic pressure develops as a result of both the volumetric expansion of freezing water and the growth of ice lenses due to migration of water. Although disputed by theoretical considerations and by experimental and field evidence (French, 1988; Mackay, 1980), differential frost susceptibility and consequent differential frost penetration and heaving may cause sedimentary deformations (Van Vliet-Lanoë, 1991). Van Vliet-Lanoë also used this mechanism to explain patterned-ground development. According to experimental data (Corte, 1971; Pissart, 1970, 1982), repeated freeze–thaw cycles may induce considerable movements of sediment. Kokelj et al. (2007) attributed a main role to the increased thickness of organic material in troughs around mud hummocks, which induces thinning of the underlying active layer and results in a bowl-shaped permafrost table below hummock centers. Ice enrichment at the top of the permafrost in the bowl leads to thrusting of soil radially inward and upward. When hummocks thaw and degrade, outward spreading of sediment at the surface completes the circular movement of the sediment.

In laterally homogeneous soils, cryostatic pressures and frost disturbance of the soil occur randomly and therefore should result in irregularly spaced structures (types 1 and 6). It is difficult to imagine how regular deformation structures could develop without preexisting regular, horizontal spatial patterns of heterogeneity. For example, frost fissures could allow differential frost penetration and induce a regular pattern of cryoturbations as defined by the fissure polygons. Likewise,

regularly spaced pockets of sediment formed by other processes, for example, type 2 loading, may also have different rates of freezing in comparison with the surrounding sediment and consequently create regular patterns of cryoturbation (Vandenberghe, 1983b).

Cryostatic pressures induce upheaval of soils in cell-like patterns controlled by the initial thermal or desiccation fissure network. Freezing of the sediment in the fissures results in lateral pressure, which may cause doming of the upper sediments in the center of the cells. In the horizontal section, the preserved structure is identical to the pattern caused by contraction polygons. This process may result in the formation of hummocks (Bohncke et al., 1993; Vandenberghe, 1988). The corresponding sedimentary deformations are classified as type 5c (Figure 1).

Cryoturbations resulting from differential cryostatic pressure apparently require a high frequency of freeze–thaw alternation rather than the existence of permafrost, except in the case of the processes reported by Van-Vliet-Lanoë (1991) and Kokelj et al. (2007).

Paleoclimatic Significance

All types of cryoturbation, except type 2, require cold conditions but not necessarily permafrost. They may be favored by repeated freeze–thaw cycles, in the case of cryostatic pressure. But with load casting (types 3 and 4) and cryohydrostatic pressure (types 5a and 5b), an impervious layer is required in order to build up the necessary conditions of oversaturation or artesian pressure. The impervious boundary in unconsolidated sediments generally corresponds with the top of a frozen subsoil. Apart from type 2 cryoturbations, this frozen subsoil may correspond with the remains of seasonally frozen ground that was still present at the time of the cryoturbation process. Therefore, all these types of cryoturbation have a limited applicability in paleoclimatic reconstruction: they simply point to frequently alternating freezing and thawing or to long-lasting and deep seasonal freezing.

Type 2 cryoturbations are particularly significant due to their large amplitude of folds. The loading process in type 2 is identical to that causing type 3 and 4 cryoturbations; but in the latter cases, it is possible, considering their small amplitude, that the deformation took place in a layer that thawed in spring. However, the large amplitudes of type 2 deformations often exceed the maximum thickness of a seasonally thawing layer. The loading process occurs when permafrost degrades and the overlying thaw layer is thicker than a seasonal thaw layer. Arguments against formation within an annual active layer (French, 1986) are the general lack of excess water in the active layer and the regularity of the type 2 deformations that would probably be destroyed if the loading process were repetitive (possibly annually). Other arguments for the presence of permafrost have been discussed above (e.g., the presence of ice-wedge pseudomorphs, the wide lateral extent, and the flat bottom of the pockets). These arguments not only point to the occurrence of a perennially frozen subsoil but also to the widespread or spatially continuous occurrence of permafrost. In conclusion, type 2 cryoturbations point to the

former presence of continuous permafrost and to formation during the degradation of that permafrost.

Paleoclimatic conditions necessary for the formation of type 2 cryoturbations are thus the same as those required for the development of continuous permafrost. Originally, a mean annual air temperature (MAAT) of less than -6°C was proposed by Péwé (1966). Later, this condition was specified in terms of subsoil lithology by Romanovskii (1985), Vandenberghe and Pissart (1993), and Huijzer and Vandenberghe (1998). A MAAT of -4°C was generally accepted as the upper thermal limit for fine-grained soils, whereas for coarse-grained subsoils, an upper limit of -8°C was assumed. It has since been argued that other factors besides temperature and subsoil lithology are influential, such as vegetation and snow thickness (Murton and Kolstrup, 2003). Van Huissteden et al. (2003) discussed in detail the potential factors that may modify the minimum paleoclimatic conditions required for the development of continuous permafrost and thus for the development of type 2 cryoturbations. It may be argued that an error bar of up to $\pm 2.5^{\circ}\text{C}$ might be applied to these cryoturbations, and thus to permafrost occurrence. In this way, the MAATs suggested earlier should be sufficient to accommodate local variations in vegetation and snow, and other deviations from present-day analogs.

Redistribution of Organic Material as a Result of Cryoturbation

The development of cryoturbations, accompanied by thickening of the active layer, moves organic matter downward, resulting in increased storage of organic carbon within the subsoil. In addition, microbial decomposition of buried organic material is delayed in comparison with that in topsoil horizons (Bockheim, 2007). The rate of carbon storage in soils is highest during the early stages of soil formation (Schlesinger, 1990). Humic-rich topsoil horizons that have subsided by cryoturbation may retain approximately their original carbon content, while the uppermost sediments may continue to undergo soil formation and accumulate new carbon (Hugelius et al., 2010; Kaiser et al., 2007). Thus, cryoturbation may promote long-term storage of carbon in the subsoil, and as such, the downsinking of C-rich topsoil may contribute significantly to the sequestration of terrestrial carbon (Kaiser et al., 2007).

A key question is: what will happen to this added store of organic carbon once cryoturbation ceases but warming continues and permafrost degrades further or disappears? Schuur et al. (2008) recognized the vulnerability of the large amounts of carbon within organic pools in permafrost, because active-layer thickening will promote microbial decomposition of previously frozen organic carbon released from the uppermost layer of permafrost. The nature and rate of this carbon release, however, are major uncertainties that are only beginning to be understood quantitatively but are beyond the scope of this contribution (Schuur et al., 2008). One approach might be to consider the evolution of the carbon pool from the last glacial cryoturbated organic layers when permafrost degraded after the Last Glacial Maximum.

Conclusion

The cryoturbation structures described earlier are linked to specific processes and environmental conditions. They may originate from (1) gravitational forces during thaw of frozen subsoil, (2) confined and pressurized water–sediment injection from between frozen parts of the subsoil, or (3) pressures due to differential frost penetration and heave. The first process occurs during degradation of underlying frozen subsoil, indicating a warm period that follows the cold period when freezing of the subsoil occurred. The other two processes occur during soil freezing, indicating cold-climate conditions.

Type 2, 3, and 4 cryoturbations, all originate by periglacial loading at the time of thawing of the underlying frozen soil. Their amplitude is a function of the depth of the impervious horizon below the surface at the time of their formation. Large amplitudes can develop above the remnant of perennially frozen ground, whereas smaller amplitudes may locally occur above the remnant of seasonally frozen subsoil.

Type 2 cryoturbations point to widespread or spatially continuous permafrost. For type 5a and 5b cryoturbations, permafrost is not necessary because an impervious horizon below the liquefied sediment is sufficient to create the required pressure in that sediment. However, in unconsolidated sediments, an impervious layer is generally absent and the permafrost table may act as such. The other cryoturbation types do not require permafrost conditions but may also occur with deep seasonal frost or frequent freeze–thaw cycles.

Cryoturbations associated with increasing active-layer thickness may contribute considerably to the redistribution of organic material and ultimately to supplementary storage of organic carbon.

Ice Wedges and Ice-Wedge Casts

J Murton, Permafrost Laboratory, Department of Geography, University of Sussex, Brighton, UK

Introduction

Ice wedges belong to a group of vein- and wedge-shaped structures that are characteristic of periglacial environments. The structures form by infilling of thermal contraction cracks in frozen ground with ice, clastic sediment or organic material. If ice within the infilled cracks melts, the resulting voids sometimes fill with soil, producing a pseudomorph or cast of the original ice structure. Such ice-wedge casts have been widely used since the 1960s to reconstruct Quaternary paleotemperatures. But recent studies of thermal contraction cracking and of the processes and structures of primary and secondary infilling indicate that the paleoenvironmental significance of relict veins and wedges is more complex than was initially understood and that many paleotemperature estimates in the Quaternary literature must therefore be treated with caution.

Thermal Contraction Cracking

When frozen ground cools, it contracts by an amount determined by the drop in temperature and the linear coefficient of thermal expansion. If the resulting tensile stress cannot be relieved by creep, the ground cracks. Thermal contraction cracking occurs in winter when ground that is already cold rapidly cools (Lachenbruch, 1962, 1966). In addition to rapid drops in air temperature, many site-specific factors influence cracking (e.g., snow cover, vegetation, creep of frozen ground and particle size; Mackay, 1993) because they affect the coefficients of thermal expansion and the rates of ground temperature change (Mackay and Burn, 2002; Yershov, 1998).

In a vertical cross section, thermal contraction cracks in old ice wedges often form narrow V shapes ~2–4 m deep and ~2–20 mm wide at the ground surface. Exceptionally wide cracks (≤ 20 cm) probably result from unusually high coefficients of thermal contraction. Cracks tend to be vertical because contraction is constrained laterally, and they taper downward because horizontal tensile stresses decline with depth (Mackay, 1974). Cracking tends to recur in the same location because previous cracks form lines of weakness. The frequency of ice-wedge cracking is highly variable, site-specific and time-dependent (Mackay, 1992).

Primary Infilling

Mechanisms and Conditions

Thermal contraction cracks may fill with snow, ice, mineral particles or organic material, according to near-surface conditions. In winter, snow may blow into cracks. In spring, meltwater from snow or ground ice may flow into them and refreeze, or crystals of hoar ice may grow on crack walls when

the air becomes warmer than the ground. But in midwinter, when temperatures in the snowpack tend to be colder than those in the underlying permafrost, sublimation may remove ice from the sides of open cracks. In polar deserts, sand often blows into open cracks, and in tundra regions, organic material may contribute to crack infilling. The cracks may narrow before infilling or close without infilling because of thermal expansion of ground in summer or plugging of cracks with ice or sediment (Mackay, 1975). As a result, the infilling materials and volumes may vary over short distances, from year to year or during a single year.

Veins and Wedges of Primary Infilling

The infilling of thermal contraction cracks produces structures of variable size and shape (Table 1). Veins are more or less uniform in width and generally < 10 cm wide, whereas wedges taper downward and have a maximum width generally > 10 cm. An important distinction is made between the infilling of an open crack (primary infilling) and infilling of a void created by melt of ice veins or wedges (secondary infilling). Wedges restricted to the active layer or to seasonally frozen ground (SFG) in nonpermafrost areas are prefixed accordingly.

Ice veins and ice wedges

An 'ice vein' constitutes the ice that fills a single thermal contraction crack, whereas an 'ice wedge' constitutes the ice that fills multiple cracks in more or less the same location within permafrost. Ice wedges usually taper downward because of their tendency to crack near their centers, the frequent confinement of cracks to wedge ice, and the downward taper of the original cracks (Mackay, 1974). Actively growing ice wedges are most common in the continuous permafrost zone (Romanovskij, 1985). Wedges that are rarely active also occur in discontinuous permafrost, remaining dormant during most years but cracking during winters that are unusually cold or deficient in snow cover. Ice wedges tend to be larger and more common in fine-grained and ice-rich sediments (or icy peats) than in ice-poor sand or gravel because of the higher coefficients of thermal expansion of icy silty clays and peats. Accordingly, smaller ice-wedge polygons often occur in finer-textured material, in ice-rich soils, or where temperature changes are marked (Black, 1974).

Three types of ice wedges can be distinguished according to ground-surface stability (Mackay, 1990, 1995). On stable surfaces, ice wedges are superimposed (epigenetic) and grow wider; on surfaces rising by sedimentation or peat aggradation, the wedges grow upward (syngenetic); and on surfaces lowering by denudation, they grow downward (anti-syngenetic; Figure 1).

Table 1 Terminology of wedges and veins^a

Ground thermal regime	Primary infilling of thermal contraction crack	Primary structure	Secondary infilling (replacement of ice with soil)	Secondary structure	Genetic interpretation
Permafrost	Ice	Ice wedge	Soil	Soil wedge ^b	Ice-wedge pseudomorph
Active layer	Ice	Seasonal ice vein	Soil	Soil vein	Active-layer ice-vein pseudomorph
				Soil wedge	Active-layer ice-wedge pseudomorph
Seasonally frozen ground (SFG) in nonpermafrost area	Ice	Seasonal ice vein	Soil	Soil vein	SFG ice-vein pseudomorph
Permafrost	Ice and soil ^c	Composite wedge	Soil replaces icy part	Soil wedge	Composite-wedge pseudomorph
Active layer	Ice and soil	Seasonal composite vein	Soil replaces icy part	Soil vein	Active-layer composite-vein pseudomorph
SFG	Ice and soil	Seasonal composite vein	Soil replaces icy part	Soil vein	SFG composite-vein pseudomorph
Permafrost	Soil	Soil wedge (e.g., sand wedge)	None		Primary permafrost soil wedge
Active layer	Soil	Soil vein (e.g., sand vein)	None		Primary active-layer soil wedge
SFG	Soil	Soil vein	None		Primary SFG soil vein

^aVeins are more or less uniform in width and generally <10 cm wide; wedges taper downward and have a maximum width generally >10 cm.

^bThe term 'soil wedge' rather than 'ground wedge' is used to describe non-icy infillings because 'ground' (as in perennially frozen ground) includes ice.

^cSoil includes all non-icy material (mineral particles, rock fragments, organic material).

Figure 1 Classification of ice wedges according to growth direction and growth sequence. Reproduced from Mackay JR (2000) Thermally induced movements in ice-wedge polygons, western Arctic coast: A long-term study. *Geographie Physique et Quaternaire* 54: 41–68; Figure 2.

Epigenetic wedges

Epigenetic wedges grow in preexisting permafrost and are younger than the host material. They grow progressively wider but little if any higher or deeper, resulting in a downward-tapering body of wedge ice. Black (1974) suggested, however, that wedges cannot widen beyond that state where their sides are inclined less than 45°, because compressive stresses cause flow and shear to occur within the wedge. The age of ice on the edges of epigenetic wedges changes little from bottom to top. Epigenetic ice wedges beneath areas of tundra commonly attain maximum widths of 0.5–2 m and depths of 3–5 m (Figure 2(a) and 2(b)). Ice wedges beneath polar deserts are rarely described in vertical section but may be smaller, due to the arid conditions and slow growth, for example, by hoar-frost accretion.

Syngenetic wedges

Syngenetic wedges grow upward as the permafrost table rises due to accumulation of sediment or peat on the ground surface. Hence, a new ice vein in a syngenetic wedge is of similar age to that of the new material in which it grows, and the age of ice on the edges of a syngenetic wedge decreases upward. Syngenetic wedges are often vertically nested in a chevron pattern, their shape determined by both the vertical and horizontal rates of wedge growth. Tall and wide syngenetic wedges develop where sedimentation continues for long periods of time, as in major floodplains (Dostovalov and Popov, 1966) or regions of thick loess (Kanevskiy et al., 2011). The largest reported syngenetic wedges, from Siberia, are 50–80 m or more high and ≤8–10 m wide (Yershov, 1998). Narrow

syngenetic wedges may form during accumulation of peat in ice-wedge troughs and polygon centers (Figure 3(b); Mackay, 1992, 2000) or aggradation of windblown sand (Figure 2(c)).

Anti-syngenetic wedges

Anti-syngenetic wedges develop where erosion progressively lowers the ground surface. Favored locations include convex sites near hilltops where the rate of active-layer movement increases downslope, and steep, bare hillslopes that recede rapidly by river undercutting. As the active layer is eroded, ice veins grow to progressively greater depths, perpendicular to the ground surface. In tandem with removal of surface material, active-layer deepening truncates the top of anti-syngenetic wedges. Thus, the age of ice on the edges of the wedges increases upward, and the growth record of old wedges is always incomplete. In hilly topography along the western Arctic coast, Canada, anti-syngenetic wedges are probably more abundant than either epi- or syngenetic ones (Mackay, 1995). They also tend to be much wider than epigenetic wedges in adjacent flattish areas; maximum true widths are commonly a few meters, with the widest >8.4 m (Mackay, 2000). Such widths may develop because less winter snow accumulates on windblown hillslopes than on most flattish areas, and so the hillslopes are probably colder and subject to more frequent cracking.

Ice-wedge growth forms may vary between adjacent sites and through time. Hilltop portions of active ice-wedge systems could be epigenetic, receding hillslope portions anti-syngenetic, and depositional areas of valley bottoms syngenetic. Epigenetic wedges growing near hilltop edges may evolve into anti-syngenetic wedges through hillslope recession, while anti-syngenetic

Figure 3 (a) Schematic diagram showing the growth of primary epigenetic ice wedges beneath a newly drained lake bottom. The tops of the wedges commence growth 0.7 m below zero datum. (b) After accumulation of 1–2 m of peat, the tops of the primary ice wedges are now 0.5 m above zero datum (the mean level of the peat–soil contact). Thus, the tops have moved upward 1.2 m, although there is no evidence for syngenetic growth. A secondary, syngenetic ice wedge has commenced growth in the polygon center. Reproduced from Mackay JR (1992) The frequency of ice-wedge cracking (1967–1987) at Garry Island, western Arctic coast, Canada. *Canadian Journal of Earth Sciences* 29: 236–248.

wedges growing near the base of receding hillslopes may evolve into syngenetic wedges if they are buried by deposition from upslope.

This threefold classification is undoubtedly useful but can be difficult to apply to some wedges. For example, many so-called epigenetic ice wedges beneath peaty, low-centered polygons grow both wider and higher due to uplift of wedge ice rather than syngenetic growth (Mackay, 1992). The ground surface adjoining epigenetic wedges rises progressively by the added volume of wedge ice and sometimes by the accumulation of peat. Field evidence for upward growth occurs where the tops of ice wedges are above the original ground surface (de Leffingwell, 1915), which in areas of long-term peat accumulation approximates to the contact between the soil and overlying peat (Figure 3(b)). Another problem sometimes arises where little is known about ground-surface stability, which can therefore make it difficult to distinguish between epi- and

syngenetic wedge growth. In this case, the term 'rejuvenated' wedge is sometimes appropriate.

Rejuvenated wedges

Rejuvenated wedges have two or more growth stages evident at their tops (Lewkowicz, 1994; Mackay, 1974). They comprise a series of nested wedges, in which a lower wedge has one or more raised tops, usually extending up from its center and often forming a pyramidal shape (Figure 2(d)). Rejuvenated wedges form when the permafrost table rises, such that ice veins in the active layer are not completely melted by summer thaw but add an increment of ice to the wedge top. Rejuvenation results from several factors, including climate cooling, accumulation of colluvial or peat deposits, unusually warm summers followed by cooler ones, or by lake drainage and regrowth of old ice wedges partially thawed beneath the former lake.

Soil veins and soil wedges of primary infilling

Soil veins and wedges of primary infilling form where mineral particles, rock fragments or organic materials accumulate in open thermal contraction cracks (Table 1). The best-known type of primary soil wedge is a permafrost sand wedge (Murton et al., 2000; Péwé, 1959). Active sand wedges are most abundant in polar deserts, where vegetation and snow cover tend to be meager or absent, promoting eolian sand transport when thermal contraction cracks are open (Bockheim et al., 2009a; Sletton et al., 2003). But sand wedges may form locally in sandy tundra with little or no winter snow cover. Small, active primary sand wedges (~ 2 m high) and veins are not restricted to permafrost but also form in active layers and, occasionally, in seasonally frozen ground.

Individual sand veins are typically 1–10 mm thick, 10–400 cm deep and occur singly or in groups known as 'bundles' and sand wedges (Figure 4). Each vein forms where sand falls into an open thermal contraction crack, often blown there. Sand wedges often vary more in shape than ice wedges because the sandy materials in which they frequently occur have tensile strengths similar to that of the sandy infill. Hence, the location of cracking in sand tends to be more variable than cracking in wedge ice, resulting in sand veins branching out from the sides and toes of sand wedges and in complex, cross-cutting relationships between bundles of sand veins within sand wedges. Epigenetic sand wedges develop in stable substrates; syngenetic bundles and wedges develop where cracking and infilling coincide with sediment aggradation, for example, within alluvial fans and eolian or fluvio-eolian sand sheets; and anti-syngenetic wedges form where the ground surface is lowering, for example, through deflation of sand and silt or sublimation of buried glacier ice (Murton and Bateman, 2007).

Soil veins and wedges of primary infilling have a high preservation potential in Quaternary sediment sequences because they contain little ground ice and therefore suffer little if any modification during permafrost degradation. As a result, relict sand wedges dating back to the Middle or early Pleistocene have been observed, for example, in southern Patagonia, where four horizons of wedges are dated from ~ 200 ka to ~ 1.0 – 1.1 Ma (Bockheim et al., 2009b). Relict wedges can often be distinguished from ice-wedge pseudomorphs (discussed later) by the occurrence of vertical to steeply dipping lamination within the wedge and by upturned strata in the host material. But there are no unique criteria to identify primary sand veins and wedges because of similarities between sand veins and wedges of diverse origins (Murton et al., 2000). Identification depends on both the occurrence of distinctive features, which are not always present (Table 2), and upon evaluation of their lithofacies context. This procedure should exclude subaqueous and warm-climate-related deformation products.

Dating of the cracking and infilling can be established in some late Quaternary sand veins and wedges of primary infilling by measuring the luminescence of their sand grains (e.g., Bateman et al., 2010; Kolstrup and Mejdahl, 1986). This method assumes that sunlight during grain transport totally bleaches any preexisting luminescence. After burial of the sand, the luminescence gradually regenerates through exposure to natural ionizing radiation. Luminescence dating of ancient or relict primary sand wedges can provide valuable

geochronological constraints to Quaternary histories (Buylaert et al., 2009; Murton et al., 1997).

Composite veins and composite wedges

Composite veins and wedges form by infilling of thermal contraction cracks with both ice and soil (Figure 5). Ice–soil mixtures may fill individual cracks, or the infill may vary over time due to changes in snow cover and eolian sand transport. Active permafrost composite wedges have been reported from Victoria Land, Antarctica, and vertical sections through active and inactive ones from western Arctic Canada. Composite veins may form seasonally in the active layer but experience thaw disturbance in summer.

Wedge development

Rates of wedge development vary substantially. Reported rates of widening of established ice wedges and sand wedges in some arctic and antarctic regions are ~ 1 – 4 mm a year, but the high variability of cracking frequency indicates large interannual variations in growth. Young ice wedges sometimes grow rapidly. For example, for the first 10 years after the draining of Lake Illisarvik, western Arctic Canada, growth rates ranged from ~ 1 to 3 cm a year, but ice-wedge growth had ceased in most of the lake bottom within 12 years because growing vegetation trapped deep snow (Mackay and Burn, 2002). Much lower growth rates occur where conditions for wedge development are marginal, as in sub-arctic peatlands.

Ice wedges, sand wedges and composite wedges develop over timescales measured in a few years to thousands of years. Their development often involves episodes of growth, inactivity and partial thaw because of changes in climate and ground-surface conditions. Fluctuations in active-layer depth produce complex histories of ice-wedge thaw and rejuvenation. Evidence for two phases of ice-wedge growth separated by early Holocene climate warming and active-layer deepening is common along the western Arctic coast, Canada (Mackay, 1995), and more complex stages of wedge growth, involving both climate change and variation in the primary infilling, are inferred from composite wedges here (Figure 5(c)).

Secondary Infilling

Ice within primary veins and wedges is susceptible to melting and replacement (secondary infilling) with soil or rock fragments. Melting results from a variety of local or regional factors that trigger thermokarst subsidence or thermal erosion. In turn, melting may initiate secondary infilling of voids left from ice or composite veins and wedges in permafrost (ice-wedge casting), in the active layer or in areas of seasonally frozen ground. Because secondary infilling processes affect the size and shape of ice-wedge-related structures in Quaternary sediments, we must consider the infilling mechanisms and conditions before we consider the paleoenvironmental significance of veins and wedges.

Mechanisms and Conditions

Thaw-consolidation processes influence sediment strength and thus the amount of infilling and type of deformation

Figure 4 Sand veins, bundles and wedges of primary infilling in vertical cross section, Mackenzie Delta region, western Arctic Canada. (a) Sand veins in sand, Crumbling Point. Pencil for scale. associated with ice-wedge casting. In a series of centrifuge modeling experiments to investigate casting processes and structures, model ice wedges melted more slowly than ground ice in the adjacent soil because of their larger latent heat effects. The experiments produced a variety of artificial ice-wedge

pseudomorphs, tunnels and involutions ([Figure 6](#); [Harris and Murton, 2005](#)). They showed that if the soil beside a melting wedge has time to consolidate, then the soil will be much stiffer when the wedge melts than it would be if the wedge melted at the same rate as the soil. Such soil is less likely to

Table 2 Characteristic features of primary sand veins and wedges

<i>Feature</i>	<i>Origin</i>	<i>Comment</i>
Sand vein (commonly 1–10 mm thick, 10–400 cm deep, sharp planar to curved sides, internally massive, truncating stratification in host sand and, commonly, other sand veins; veins may bifurcate and rejoin and are commonly laterally and vertically discontinuous)	Filling of individual thermal contraction crack	Host strata adjacent to sand veins are generally undeformed because of the negligible volume of sand infill added to the ground
Vertical to steeply dipping lamination, sometimes arranged in bundles	Filling of numerous thermal contraction cracks	Group of sand veins, sometimes as mineralogically or texturally distinct bundles within sand wedges. But some sand wedges or parts of them appear on close field examination to be massive, even in wind-etched exposures, because sand source was texturally and mineralogically very uniform
Sand veins extending from the sides or toes of wedges in sand (apophyses)	Variation in location of infilled thermal contraction cracks	Tensile strength of the wedge and host sand is similar, allowing more variation in the location of thermal contraction cracking than is typical of cracking of ice wedges in soil
Inclusions of host material are sometimes cross-cut by sand veins	Variation in location of thermal contraction cracking	As above
Sand grains are often more rounded (some like millet seeds) and, seen under scanning electron microscope, may contain more upturned plates, dish-shaped concavities and an 'orange-peel texture' than grains in host material	Eolian abrasion of sand infill is greater than that of host material	Sand grains of infill often resemble those of eolian sand sheets or dunes. Sand is commonly fine- to medium-grained and moderately well sorted
Pebbles or granules, where present, are generally concentrated at or near the top of sand wedges and any gravel content very distinctly decreases with depth	(1) Smaller particles fall furthest down thermal contraction cracks; (2) the limited crack width can act as a filter mechanism, restricting the larger-sized material to the upper part of the wedge	
Upturned strata in host material adjacent to sand wedges	Addition of wedge material to permafrost and ground expansion in summer	Downturned and undeformed strata are more unusual. Downturned strata in massive ice may reflect creep of ice in response to greater density of sand. Downturned strata in sand may result from folding associated with lateral compression during wedge growth. Sometimes both up- and downturned strata occur beside different parts of the same wedge. Undeformed strata adjacent to sand wedges are difficult to explain. Initial loose packing and high void ratios might contribute toward accommodation space
Ventifact lags commonly extend laterally from tops of sand wedges	Eolian abrasion	Strong winds that transported sand to thermal contraction cracks caused deflation and abrasion of adjacent material
Large-scale polygonal network of wedges	Thermal contraction cracking	

deform than unconsolidated soil with porewater pressures in excess of hydrostatic. Sand consolidates almost instantaneously, and therefore excess pore pressures are unlikely. Clay consolidates more slowly and may generate excess pore pressures during thaw, making the clay soft and deformable. Hence, secondary infilling in the experiments occurred to a greater degree in clayey and icy soils (Figure 6(e) and 6(f)) than in sandy or silty soils that contained less ice (Figure 6(a)–6(d)).

Secondary infilling of tunnels thermally eroded through ice wedges occurs by subsidence or collapse of material from tunnel walls and roofs, or by transport of material along tunnels by flowing water or colluvial processes (Figure 7). Secondary infilling is often episodic and interrupted or

counteracted by refreezing of water. For example, after episodes of thermal erosion of ice-wedge terrain (e.g., Fortier et al., 2007), water often refreezes in underground cavities within wedge ice to form 'pool' ice. Furthermore, active-layer deepening during unusually warm summers or episodes of warmer climate may be counteracted later by ice-wedge rejuvenation during cooler summers or climates. Where the wedge ice melts completely, infilling of tunnels and surface troughs may continue after melting has ceased, as indicated by voids within ice-wedge pseudomorphs and troughs above them (Romanovskij, 1973). Thus, the final pseudomorph may develop over a variable and sometimes long period of time, complicating attempts to date ice-wedge melting and secondary infilling.

Figure 5 Composite wedges of epigenetic type, Mackenzie Delta region, western Arctic Canada. (a) Alternating ice veins and sand veins within a composite wedge, Hadwen Island. Pencil for scale. (b) Composite wedge along the side of a sand wedge penetrating massive ice, Mason Bay, Richards Island. Hand for scale. (c) Composite wedges penetrating massive ice and icy sediments, Crumbling Point. Ice veins and sand veins similar to those in (b) occur along the sides of both wedges, truncated at a depth of ~ 2 m. Both wedges commenced growth as composite wedges, continued as sand wedges and were then interrupted by active-layer deepening during the early Holocene. The wedge on the right recommenced growth by ice-wedge development at a stratigraphically higher level during the late Holocene. Person for scale. (a and b) © 2006, Photograph by J. B. Murton. (c) Reprinted from Murton JB, Worsley P, and Gozdzik J (2000) Sand veins and wedges in cold aeolian environments. *Quaternary Science Reviews* 19: 899–922.

Melting of ice veins or wedges does not always lead to secondary infilling (Dylik, 1966). For example, syngenetic ice wedges tens of meters high in very ice-rich silts are unlikely to produce pseudomorphs, except perhaps in their toes, because the silts become liquid like on thawing and prone to reworking and erosion.

Soil Veins and Wedges of Secondary Infilling (Pseudomorphs)

Soil veins and wedges of secondary infilling preserve, to varying degrees, a record of the size and shape of the original ice structures. Preservation varies due to thaw consolidation, lateral movement of host material or tunnel collapse. Hence, structures of secondary infilling preserve imperfectly the original ice-wedge features and so are best termed ‘pseudomorphs’ (Table 1; Péwé et al., 1969). The term ‘cast,’ which is widely used in the Quaternary and periglacial literature, is rather misleading because it implies exact preservation of the size and shape of the ice wedge (Harry and Gozdzik, 1988). Such

preservation is of course impossible to determine where no ice remains. Moreover, exact preservation of an original roof of sediment after the underlying wedge has melted remains to be demonstrated.

Characteristics of Cenozoic-age pseudomorphs

The characteristic features of ice-wedge pseudomorphs and composite-wedge pseudomorphs of Cenozoic age are listed in Table 3 and illustrated in Figure 8. Seldom, however, are all of the characteristics found together in a single stratigraphic section.

Pseudomorphs have infills comprising material similar to that beside or above them. This similarity results from subsidence of the host or overlying material into space left by melting wedge ice. The effects of subsidence are clearest where a distinctive horizon such as peat, paleosol or tephra downturns toward or into a pseudomorph. Depending on the nature of the host sediment and the processes of ice-wedge casting, pseudomorph infills can be massive or stratified, the

strata comprising indistinct vertical to steeply dipping layers or concave-up layers. The layering in ice-wedge pseudomorphs can often be readily distinguished from the fine vertical lamination associated with soil wedges of primary infilling (Figure 4). In composite-wedge pseudomorphs, however, layering formed at different times by primary and secondary infilling may be preserved. Some pseudomorphs contain clasts or faulted blocks of sediment too large to have entered into thermal contraction cracks no wider than a few centimeters; such clasts are therefore attributed to secondary infilling. Elongate clasts may become vertically aligned by slipping down into the narrow gap beside inward-melting ice wedges. Water

seeping down such gaps may carry fine sediment with it, depositing a 'lining' along the sides of pseudomorphs. Some pseudomorphs may contain tunnels or tunnel infills. Normal faults or downturned layers commonly occur in stratified sediments adjacent to pseudomorphs, as a result of loss of lateral support of the host sediment adjacent to melting ice wedges. Finally, pseudomorphs often form a polygonal network, sometimes clearly depicted on aerial photographs by patterns of differential crop growth.

Distinguishing ice-wedge pseudomorphs from wedges of primary infilling or wedge-like structures unrelated to thermal contraction cracking is based on criteria listed in Tables 2 and 3.

Figure 6 Photographs and annotated drawings of artificial ice-wedge pseudomorphs, tunnels and involutions excavated in vertical sections following simulation of ice-wedge casting in a large geotechnical centrifuge. (a) Model 1 (medium sand, 15% gravimetric moisture content). (b) Model 2 (medium sand, 20% moisture, undrained). (c) Model 3 (Pegwell Bay silt, 40% moisture content). (d) Model 4 (Pegwell Bay silt, 20% moisture content). (e) Model 5 (2:1 by weight silt-clay mixture, 30% moisture content). (f) Model 6 (2:1 by weight silt-clay mixture, 60% moisture content). The models indicate that the degree of soil deformation during casting increased as the host sediments became finer-grained and more ice-rich. In other words, the ice-wedge shape was generally best preserved in sand, and most modified in clayey silt. Reproduced from Harris C and Murton JB (2005) Experimental simulation of ice-wedge casting: Processes, products and paleoenvironmental significance. In: Harris C and Murton JB (eds.) *Cryospheric Systems: Glaciers and Permafrost*, pp. 131–143. Special Publication 242. London: Geological Society.

Figure 6 (Continued)

Structures superficially similar to ice-wedge pseudomorphs – for example, solution pipes and tree-root casts – are easily identified by excavating the host material to determine their three-dimensional geometry and composition. But problems may arise when distinguishing between infilled thermal contraction cracks and desiccation cracks in the case of small soil veins and wedges ($\sim < 1$ m high) in silts or clays. The distinction between sand wedges of primary infilling and sand wedges of secondary infilling where upturned strata flank wedges whose fill is massive, well-sorted sand is also problematic (Black, 1976).

Some pseudomorphs develop through a combination of infilling conditions or mechanisms. Active-layer soil wedges ~ 0.1 – 0.5 m wide and ~ 0.3 – 2.3 m deep from Siberia, Spitsbergen and northern Quebec have been attributed to secondary infilling during melt of seasonal ice veins, without a contribution from melting of underlying ice wedges. Some infilling can certainly occur in summer as meltwater allows

soil or rock fragments to flow or slide into voids, producing indistinct vertical layers within soil wedges; consistent with this interpretation are remnants of seasonal ice veins observed at the summer thaw front in soil wedges. But the seasonal interpretation has rightly been questioned where soil wedges overlie ice veins or wedges within permafrost, because the bottoms of the soil wedges may develop where the tops of the ice wedges have melted. Distinguishing between melt of seasonal ice veins and melt of underlying permafrost ice wedges is difficult because active-layer depth varies from year to year and ice-wedge rejuvenation is common. Two conclusions arise. First, active-layer soil wedges form by secondary infilling in different ways, including (1) melt of seasonal ice veins, (2) melt of underlying ice-wedge tops, (3) complete melt of ice wedges and erosion of the tops of ice-wedge pseudomorphs, or (4) a combination of them. Second, some so-called ice-wedge pseudomorphs are probably compound structures,

Figure 7 Partially thawed ice wedges and associated pseudomorphs, Mackenzie Delta region, western Arctic Canada. (a) Photograph and diagram of a partly filled tunnel into which a mat of peat and tundra vegetation has subsided where an ice wedge has melted completely at a coastal bluff, Hendrickson Island. Just 3 m inland (not shown), the top of the same ice wedge is at a depth of 45 cm. (b) Photograph and diagram of a tunnel infilled by blocks of fallen sand above a partially thawed ice wedge, Hadwen Island. Reproduced from Murton JB and French HM (1993) Thaw modification of frost-fissure wedges, Richards Island, Pleistocene Mackenzie Delta, western Canadian Arctic. *Journal of Quaternary Science* 8: 185–196.

the lower part comprising a pseudomorph after a permafrost ice wedge, and the upper part an active-layer soil wedge formed by melt of seasonal ice veins.

Composite-wedge pseudomorphs form by a combination of primary and secondary infilling, and therefore share features with both primary soil wedges and ice-wedge pseudomorphs (Figure 9; Ghysels and Heyse, 2006; Gozdzik, 1973). Where composite wedges contain little ice, their pseudomorphs are difficult to distinguish from primary sand wedges. It is likely that some structures interpreted as ice-wedge pseudomorphs in the Quaternary literature are instead composite-wedge pseudomorphs, especially where former vegetation cover was sparse, favoring a combination of blowing soil and snow during winter.

The variable shape and size of pseudomorphs complicates their identification. Pseudomorphs that taper uniformly

downward like a typical epigenetic ice wedge (Figure 8(a)–8(f)) are easier to identify than pseudomorphs that are irregular (Figure 8(g) and 8(h)). Such irregularity often results from slumping, thermal erosion and rejuvenation of wedges. In terrain subject to thermal erosion and refreezing of water-filled cavities, melting of ice wedges truncated by irregular bodies of pool ice may produce irregular pseudomorphs, although their preservation potential is uncertain. Melting and secondary infilling of rejuvenated ice wedges may also produce irregular and complex pseudomorphs. In terms of size, pseudomorphs vary in maximum width from a few millimeters to a few meters and in height from a few tens of centimeters to several meters, although truncated pseudomorphs are common. Small, narrow pseudomorphs are often the most difficult to identify because melt of ice veins in cohesive materials does not always lead to downturning or faulting of adjacent sediment.

Table 3 Characteristic features of ice-wedge pseudomorphs and composite-wedge pseudomorphs

<i>Pseudomorph characteristics</i>	<i>Suggested origin</i>	<i>Comment</i>
Infill is similar to material above or beside it	Subsidence of host or overlying material into space formed by melting ice wedge	
Massive infill, often poorly sorted and lacking systematic vertical trends in particle size. Vertical to steeply dipping layers, often indistinct, within some pseudomorphs	Collapse of overlying or adjacent sediment into void	Infill often has a chaotic appearance and may be looser than host material
Vertical to steeply dipping layers, often indistinct, within some pseudomorphs	Subsidence of adjacent, stratified host material	Layers tend to be thicker than veins of primary infilling and can often be traced upward and then sideways, joining the adjacent host strata, which therefore precludes primary infilling
Concave-up sediment layers, stacked within gravelly pseudomorphs	Gradual subsidence or slumping of overlying material during downward melt of ice wedge	Observed in some large ice-wedge pseudomorphs within stratified fluvial sand and gravel
Large clasts or faulted blocks of sediment within pseudomorph	Subsidence or slumping	Material is too large to have entered into original crack by primary infilling
Elongate clasts are vertically to steeply aligned within pseudomorph	Realignment of elongate clasts in narrow gap along sides of inward-melting ice wedge	Common in gravel or diamicton sequences
Lining: a layer of fine sediment along the sides of pseudomorphs	Deposited by water seeping down the sides of melting ice wedges	Tends to form near bottom of pseudomorphs
Tunnels or irregular voids infilled to various degrees	Tunnels often develop by thermal erosion of ice-wedge ice and then infill to varying degrees with sediment	Tunnel infill is often poorly consolidated
Polygonal configuration in plan	Thermal contraction cracking	Polygons are sometimes seen in vegetation patterns on aerial photographs. Polygons are characteristic of wedges of both primary and secondary infilling but are not always present during early stages of wedge development
<i>Adjacent host material</i>		
Downturned strata	Subsidence due to loss of lateral support as ice wedge melts	Downturning does not always occur, and traces of original upturned strata are sometimes preserved, especially in thaw-stable or very cohesive hosts (e.g., brecciated bedrock, peat, compact clay); infilling occurs mainly from above
Normal faults, often stepped	Brittle failure associated with subsidence or collapse of host material	Common in sand

Paleoenvironmental Significance of Veins and Wedges

Relict Ice Wedges

Ice wedges can persist in permafrost environments for decades to many thousands of years after they cease to crack and grow. Such inactive or relict wedges are widespread in permafrost sedimentary sequences in arctic and sub-arctic lowlands of Canada, Alaska and Siberia, with the oldest known wedges probably exceeding 740 000 years in age (Froese et al., 2008), in contrast to some Holocene wedges that have only been inactive during the twentieth century (Kokelj et al., 2007). Analysis of the crystallography and stable oxygen and hydrogen isotopes of the ice and of the gas composition (O_2 , N_2 , Ar) of air entrapped in the ice can elucidate the source and mechanism of infill of the ice wedges. From these analyses, inferences can be drawn about past moisture and winter

temperature conditions (e.g., Popp et al., 2006; St-Jean et al., 2011; Streletskaia et al., 2011).

Ice-Wedge Pseudomorphs

Ice-wedge pseudomorphs are frequently used to estimate former maximum values of mean annual air temperature (MAAT) and the mean temperature of the coldest month (MTCM). Widely used estimates are $\leq -4^\circ\text{C}$ and $\leq -8^\circ\text{C}$ (to -6°C) for the MAAT associated with fine-grained and coarse-grained substrates, respectively, and $\leq -20^\circ\text{C}$ for the MTCM. The widespread use of ice-wedge pseudomorphs as paleotemperature indicators arose from studies of ice wedges in Alaska (Péwé, 1966). There, the area of active ice wedges approximates the continuous permafrost zone, and has a MAAT ranging from $\sim -6^\circ\text{C}$ to -8°C in the south to $\sim -12^\circ\text{C}$ in the north. Péwé (1966) concluded that “[i]f ice wedges can be

proven to have existed in the geologic past in a particular area, it can be broadly assumed that, at the time of ice-wedges formation, a rigorous permafrost environment existed with a [MAAT] in the vicinity of -6 to -8 °C, or colder."

Unfortunately, several problems bedevil the Holy Grail of a simple relationship between ice-wedge growth and MAAT (Harry and Goździk, 1988; Murton and Kolstrup, 2003). First, many site-specific and time-dependent factors influence cracking and wedge development. Second, it is the rapidity and amount of temperature change in the upper few meters of frozen ground, rather than the air temperature, that is important to cracking. Because ground-surface temperatures in northern latitudes differ from MAATs by variable amounts (often ~ 1 – 6 °C), depending on near-surface factors such as snow cover and vegetation, "no simple relationship exists (between cracking and MAAT) except that colder temperatures regionally promote more contraction cracking" (Black, 1976). Third, ice-wedge cracking occurs in winter, whereas MAAT also takes into account temperatures in summer. Fourth, the long periods over which MAATs are compiled may conceal significant short-term climatic variation. Rare, unusually cold winters allow intermittent ice-wedge growth in the discontinuous

permafrost zone. This explains why the maximum proposed value of MAAT at which ice-wedge cracking can occur has increased from Péwé's original value of -6 to -8 °C to values of -4 °C or -3.5 °C. In conclusion, ice-wedge pseudomorphs simply indicate the former occurrence of permafrost: most likely, but not inevitably, continuous permafrost.

Relict Primary Sand Wedges

Relict primary sand wedges indicate the former occurrence of (1) sand transport, often by wind, during winter or spring; and (2) little or no snow cover, for otherwise the cracks may fill with ice or ice–sand mixtures. These conditions have generally been attributed to (1) climatic aridity in polar deserts or steppe tundra; (2) dry, windswept environments marginal to Pleistocene ice sheets; (3) edaphic aridity due to an absence of permafrost; (4) locally dry surface conditions such as exposed, elevated areas and well-drained, coarse-grained sediments or simply local areas where plenty of wind and a sand source are available; and (5) widespread ground instability and sparse vegetation cover due to active geomorphic processes and rapid climatic change (Murton et al., 2000).

Figure 8 Ice-wedge pseudomorphs in deposits of Cenozoic age. Large pseudomorphs are common in periglacial fluvial sand and gravel, as shown from (a) Whisby quarry, near Lincoln, England (spade for scale); and (b) Cassington quarry near Oxford, England (survey tripod for scale). In relatively homogeneous sediments, pseudomorphs can be marked out by distinctive downturned layers, such as (c) gray gleysol in reworked loess, Kesselt, Belgium (spade for scale); and (d) white tephra in gravel, ~ 35 km southeast of Dawson City, Yukon, Canada (knife and axe for scale). (e) Vertically aligned to steeply dipping clasts within pseudomorph from Sewerby, East Yorkshire, England (2.75 m high section). (f) The smallest pseudomorphs are veins of secondary infilling, as shown by sand veins from the Dinkel valley, the Netherlands (pen for scale). (g and h) Deformed, irregular pseudomorphs in gravel, Donnelly Dome area, Alaska. (a–f) © 2006, Photographs by JB Murton. (g and h) Reproduced from Pewe TL, Church RE, and Andresen MJ (1969) *Origin and Paleoclimatic Significance of Large-Scale Patterned Ground in the Donnelly Dome Area, Alaska*. Special Publication 103. Boulder, CO: Geological Society of America.

Figure 8 (Continued)

Relict primary sand wedges >2 m high and with well-developed vertical lamination usually indicate the former occurrence of continuous permafrost. This inference is based on the maximum reported depth of seasonal frost cracks (~2 m) and the occurrence of repeated cracking and infilling, which is most likely where permafrost is continuous.

Soil Veins and Small Soil Wedges

Relict soil veins and small wedges indicate the former occurrence of thermal contraction cracking but do not distinguish between permafrost, active layers or seasonally frozen ground. Maarleveld (1976) inferred a MAAT of 0 °C for narrow frost cracks (soil veins) in Pleistocene sediments of the central Netherlands, and a MAAT of between 0 and –6 °C for larger frost cracks transitional with ice-wedge pseudomorphs. Such estimates, however, are of questionable validity, not only for reasons discussed earlier, but also because soil veins and small soil wedges are found throughout contemporary cold regions.

Selective Preservation

Paleoenvironmental interpretation of relict veins and wedges is biased by their selective preservation in the geological record. Primary soil veins and wedges have the highest preservation

potential due to the paucity or absence of ice within the infill; thaw-related disturbance occurs only where soil wedges penetrate ice-rich materials. Ice wedges tend to be larger or more common in ice-rich silts, clays or peats, whereas their pseudomorphs form preferentially and are better preserved in ice-poor sand and gravel, which deform little during melt of constituent ice wedges (Black, 1976). Such selective preservation has probably led to an underestimation of the number of ice-wedge pseudomorphs in fine-grained soils that were originally ice-rich. This biases reconstructions toward colder temperatures.

Another form of selective preservation favors identification of former ice wedges with simple shapes. Because of thaw disturbance, the preservation potential of syngenetic ice wedges with serrated edges or of rejuvenated ice wedges with pyramidal tops is probably much less than wedges with a simple V shape.

Conclusions

Thermal contraction cracks may fill with surface materials, narrow before infilling, or close without infilling. Infills comprise ice, mineral particles or organic material, and form a variety of veins and wedges of primary infilling (Table 1). Different types of wedges develop according to the stability of the ground surface and permafrost table. Melt of ice veins and wedges sometimes initiates secondary infilling of the space left by

Figure 9 Composite-wedge pseudomorph in sands of the Cromer Forest Bed Formation, near Trimingham, north Norfolk, England. The central (orange) part of the wedge comprises well-sorted, vertically laminated sands typical of a sand wedge of primary infilling, whereas the outer part – in the host sand – comprises step normal faults typical of secondary infilling associated with the formation of an ice-wedge pseudomorph. The black horizon near the top is the Cromer Forest Bed. The exposed wedge is ~2 m high. © 2006, Photograph by R.J.O. Hamblin. Published with permission of the British Geological Survey. The wedge is described in Fish PR, Carr SJ, Rose J, Hamblin RJO, and Eissmann L. 1996. A periglacial composite wedge cast from the Trimingham area, North Norfolk, England. *Bulletin of the Geological Society of Norfolk* 46: 11–16.

melting ice. The resulting ice-wedge pseudomorphs provide reliable evidence for the former occurrence of permafrost but they do not provide reliable quantitative estimates of MAATs. A more promising field of quantitative paleoenvironmental study that remains to be fully explored concerns the inferences that could be drawn from detailed analyses of the primary infillings of large syngenetic and anti-syngenetic wedges, particularly in terms of isotopes, organic material and eolian sand.

Patterned Ground

Introduction

The term *patterned ground* describes terrain that exhibits regular or irregular surface patterning, most commonly in the form of circles, polygons, irregular networks, or stripes. Step-like, oval, lobate, and garland patterns are also sometimes referred to as patterned ground. Following Washburn (1956), most investigators have recognized a distinction between *sorted patterned ground* produced by the alternation of soil and coarse debris at the ground surface, and *nonsorted patterned ground* defined by microrelief (alternating mounds and depressions, or ridges and furrows) or vegetation cover (alternating vegetated and unvegetated ground). Although various forms of ground patterning occur in a range of environmental settings, most patterned ground is associated with periglacial environments where recurrent freezing and thawing of moist soil is the dominant formative mechanism, though neither permafrost nor severe winter cold is required for the formation of all periglacial patterned ground types. Active patterned ground produced by ground freezing and thawing occurs in high-latitude permafrost environments, in subarctic areas subject to deep seasonal ground freezing, on alpine and high subtropical mountains, and on mountains in cool temperate environments. Certain forms of patterned ground produced by shallow ground freezing also occur at low altitudes in cool temperate environments (e.g., Ballantyne, 1996), but these are usually small-scale features that have formed under exceptional circumstances. On exposed plateaus, the interplay of wind scour, loosening of soil particles by frost, and selective vegetation growth also results in the development of surface patterns in the form of clumps, crescents, ribbons, and stripes of vegetation amid unvegetated stony ground (Ballantyne and Harris, 1994, pp. 260–261), but such wind-patterned ground is genetically unrelated to patterned ground created by freezing and thawing of the soil and so, it is not considered further here.

Most research on periglacial patterned ground has involved the study of mature landforms, and the processes responsible for pattern initiation have often been inferred from present-day pattern characteristics, internal structure, and measurement of soil and clast displacement. There has also been a tendency for studies to focus on individual pattern types, leading to numerous theories of pattern origin. Washburn (1956), for example, examined 19 hypotheses for pattern initiation and development and inferred a multiplicity of formative mechanisms. Recent numerical modeling of ground freezing and thawing, however, suggests that most periglacial patterned ground has been initiated by differential frost heave of frost-susceptible soil, and that the differences between sorted patterns and nonsorted patterns may reflect initial conditions, particularly the presence or absence of vegetation cover and the abundance of clasts. *Frost heave* is uplift of soil due to the formation of lenses of segregated ice in fine-textured soils and *differential frost heave* is laterally nonuniform frost heave,

which produces an undulating surface microtopography. The application of linear stability analysis to freezing soils (Kessler et al., 2001; Peterson, 2011; Peterson and Krantz, 2003, 2008) has demonstrated that one-dimensional frost heave is unstable under a range of boundary conditions and tends to develop into differential frost heave, with the eventual development of a dominant modal wavelength that determines pattern spacing. Various feedback processes, still incompletely understood, are thought to enhance the initial perturbation caused by differential frost heave, permitting the eventual development of both sorted and nonsorted ground patterns.

Sorted Patterned Ground

Characteristics

Sorted patterns develop on unvegetated or sparsely vegetated terrain where abundant clasts overlie or are embedded in fine soil. On level or gently sloping ground, sorted patterns usually consist of cells or domains of predominantly fine soil surrounded by stony borders that in the thawed state may be depressed or raised relative to the fine centers (Figures 1–3), though in active patterns, the fine cell is often heaved above the level of surrounding clasts during winter freezing. These concentrations of clasts often take the form of regularly spaced sorted circles or polygons, or an irregular sorted net or labyrinth of clasts separating fine cells of varying size and shape. Less commonly, stone pits develop, characterized by concentrations of clasts surrounded by raised borders of fine-grained sediment. All sorted patterns tend to become increasingly elongated along the direction of maximum gradient as slope angle increases, grading downslope into sorted stripes consisting of alternating bands of fine and coarse debris (Figure 4).

Reported pattern widths of sorted nets, circles, polygons, and stripes range from about 10 to 20 m, though accounts of forms exceeding 4 m in width are rare and probably reflect the concentration of clasts into the troughs of ice-wedge polygons (see below). Pattern width is often related to the coarseness of clasts that define the pattern margins (Goldthwait, 1976): patterns defined by small pebbles rarely exceed 0.4 m in width, and patterns defined by bouldery margins usually exceed 1–2 m in width. Within the coarse borders, clast size tends to diminish with depth, and in active patterns, clasts in pattern borders are often erect (standing on end) as a result of lateral pressures exerted during freezing and expansion of fine centers in winter (Figure 5). In permafrost environments, striking examples of large sorted circles (Figure 6) consist of a central slightly domed plug or cylinder of fine soil 2–3 m wide surrounded by an annulus of gravel that rises up to 0.5 m above the soil domain (Hallet and Prestrud, 1986; Washburn, 1989), with both the central plug and surrounding gravel rings extending downward to the underlying permafrost table. Elsewhere, sections excavated through both small- and large-scale sorted

Figure 2 Large-scale sorted net (pattern widths 2–4 m) developed on a periglacial blockfield at 1700 m on Mount Bitterness, St Mary's Range, South Island, New Zealand.

Figure 3 Sorted nets 0.6–1.1 m wide at a site of intermittent flooding, Jotunheimen Massif, south-central Norway.

Figure 4 Active sorted stripes with a pattern width averaging 0.6 m developed on felsite regolith at 600 m on Tinto Hill, southern Scotland. These stripes are believed to have formed through a combination of shallow ground freezing and differential needle-ice growth with concurrent downslope migration of both clasts and fine soil. When this site was dug over to a depth of 0.3 m, stripes reformed within 3 years.

Figure 5 Erected clasts at the margin of a large sorted net on Mount Bitterness, St Mary's Range, South Island, New Zealand. Clast erection is due to lateral pressures exerted on the coarse border during winter freezing and expansion of adjacent fine sediments.

patterns often show that clasts forming coarse borders occupy V-shaped troughs in finer soil. Sorted patterns may be active (largely unvegetated and subject to displacement of both fine sediment and clasts as a result of recurrent ground freezing and thawing; [Figures 1–6](#)) or relict features with vegetated fine-grained cells and lichen-covered bouldery margins ([Figure 7](#)). Relict large-scale patterns defined by boulders have often survived intact throughout the Holocene ([Ballantyne and Harris, 1994](#); [Grab, 2002](#)), but small-scale patterns have limited preservation potential. Some sorted patterns exhibit secondary

sorting, with decimetric patterns defined by smaller clasts forming inside the fine domain of a larger sorted circle, net, or polygon.

Formation

Most researchers have envisaged the development of sorted patterns in terms of a circulatory model involving upward and/or outward movement of sediment in cells, migration of surface and near-surface sediment from cells to adjacent borders, and compensatory movement of soil toward cell centers at depth. Sorting occurs when sediment moving outward toward the margins at or near the soil surface is coarser than that moving inward toward cell centers at depth. Measurements of sediment displacement on and within active sorted circles (Hallet, 1998; Washburn, 1989) appear consistent with this general model. Sorted stripes develop on slopes because a downslope component of sediment movement is superimposed on the soil circulation. There is, however, less consensus regarding the processes driving sediment movement. Three main groups of theories have emerged: sorting by differential frost heave, sorting by buoyancy-driven soil circulation, and sorting associated with free convection of soil porewater during thaw.

Differential frost heave

A long-established view is that lateral displacement of clasts toward pattern margins and fines toward pattern centers reflects an uneven penetration of freezing planes into the ground, resulting in differential frost heave and migration of clasts away from zones of impeded freezing (Nicholson, 1976). Once established, this effect should be self-perpetuating, as the freezing plane will tend to descend more rapidly below zones of clast concentration than below intervening cells of fine sediment, where formation of ice lenses and associated release of latent heat slows the downward passage of the freezing front. The initial development of inclined freezing planes in nonsorted ground has traditionally been explained in two ways: The first involves contraction cracking of the ground surface as a result of rapid cooling or desiccation. The resulting contraction cracks act as loci of rapid ground freezing so that clasts migrate toward and become concentrated in the cracks, forming sorted polygons (Ballantyne and Matthews, 1983). The second, termed ‘primary frost sorting’ by Goldthwait (1976), proposes that randomly spaced concentrations of finer sediment freeze more slowly than surrounding soil, generating inclined freezing planes. Recurrent upward and outward frost sorting of clasts away from such concentrations of finer soil then progressively enhances the textural contrasts between these and adjacent ground. Additionally, because of their greater frost-susceptibility (propensity for ice-lens formation), such concentrations of finer sediment are liable to greater frost heave than surrounding soil so that upheaved clasts undergo gravity-induced creep toward cell margins. Sorted circles or sorted nets may initially be formed, but it is possible that the interaction of adjacent fine cells may ultimately produce sorted polygons. These concepts have been further developed by Van Vliet-Lanoë (1988), who proposed that formation of sorted polygons and contiguous sorted circles is associated with soil cracking and positive frost-susceptibility gradients (reduction in frost-susceptibility with soil depth), whereas isolated or coalescing sorted circles form on soils characterized by negative frost-susceptibility gradients.

An alternative explanation for the role of differential frost heave has been developed by Kessler et al. (2001), who proposed that large-scale sorted circles are self-organized patterns that emerge spontaneously due to the inherent instability of one-dimensional annual frost heave of the active layer, the zone of seasonal freezing and thawing that overlies permafrost. Their model assumes an initial state with a 1-m-thick active layer initially comprising a layer of stones overlying a layer of frost-susceptible soil. They argued that slight positive (i.e., updomed) perturbations at the stone–soil interface are progressively enhanced by the movement of soil inward under the site of the perturbation during freezing (Figure 8), whereas soil movements during thaw are vertical (because of lateral confinement) so that there is a small net increment of soil added under the site of the perturbation with each freeze–thaw cycle. Kessler et al. (2001) argued that this positive feedback is modulated by a concurrent negative feedback, because a descending freezing front will penetrate positive soil perturbations before adjacent regions, pushing soil toward unfrozen regions that surround the perturbation. This negative feedback favors the development of long-wavelength perturbations, achieved through the merger of initial perturbations, until wavelength

(spacing) stabilizes, limited by soil redistribution rate. Through a process of net soil accretion driven by recurrent annual freeze–thaw cycles, the dominant perturbations form soil plugs that slowly rise through the overlying stones toward the surface, expanding both upward and outward. Emergence of soil plugs is followed by updoming and radial expansion of fine soil at the surface, pushing stones to the margins of the plugs until all the soil from the underlying layer is depleted. After formation, sorted circles are maintained by differential frost heave-driven circulation within the soil and stone domains (Figure 9). Kessler et al. (2001) showed that their model successfully replicates large-scale sorted circles with a mean spacing of 3.6 m, comprising a 2.4-m-wide soil domain surrounded by a 1.0-m-wide, 0.3-m-high ring of stones, representing 750 years of annual freeze–thaw cycles, dimensions,

Figure 8 Conceptual model of patterned ground initiation by differential frost heave proposed by Kessler et al. (2001). During annual freezing of the active layer, frost heave drives material away from the freezing front (dashed line) at a small positive perturbation between a layer of soil and an overlying layer of stones. Movement is both outward toward the ground surface and inward toward unfrozen soil. As soil displacements are not reversed during thaw, this mechanism promotes upward growth of a plug of soil over recurrent freeze–thaw cycles. Reproduced, with permission, from Kessler MA, Murray AB, Werner BT, and Hallet B (2001) A model for sorted circles as self-organized patterns. *Journal of Geophysical Research* 106(B7): 13287–13306. ©2001 American Geophysical Union.

and timing that are consistent with those of the large-scale sorted circles investigated by Hallet and Prestrud (1986) in Spitsbergen (Figure 6).

The validity of differential frost heave as a sorting mechanism is well established for shallow sorted patterns with widths <1.0 m, depths <25 cm, and borders dominated by clasts <15–20 cm in length. For such small-scale patterns, the dominant sorting mechanism often appears to be differential needle-ice growth (e.g., Ballantyne, 1996, 2001; Matsuoka et al., 2003). Surface or near-surface ice needles (elongated ice crystals that grow perpendicular to the surface slope) form where the temperature of moist surface soil is reduced to freezing point by radiative cooling. Needle-ice spicules, commonly 2–20 cm in length, frequently form in environments dominated by short-term (mainly diurnal) freezing cycles. The development of small-scale sorted patterns in such environments is constrained by vegetation cover and soil texture: patterns develop only in unvegetated, fine-grained, frost-susceptible soils that permit porewater to be drawn upward to feed needle-ice growth, and where clast size is small relative to pattern dimensions. During freezing, needle ice grows under surface clasts, raising them above the level of the ground surface. As needle ice develops preferentially above patches of fine-grained soil, the layer of upraised clasts forms alternating hummocks and depressions. During thaw, there is preferential movement of clasts into depressions so that over successive cycles of needle-ice growth and decay, the textural differences between fine and coarse soil domains become progressively enhanced until sorted patterns are formed (Figure 10). This may happen quite rapidly. At a site in Scotland, for example, a small-scale sorted net developed in frost-susceptible soil as a result of differential needle-ice growth and differential frost heave in eight freeze–thaw cycles (Ballantyne, 1996), and small-scale sorted stripes attributed to a combination of differential needle-ice growth and downslope migration of sediment have been found to re-form on cleared ground within three winters (Ballantyne, 2001; Figure 4).

Werner and Hallet (1993) have developed a two-dimensional computer simulation of sorted stripe development on the basis of differential needle-ice growth. Their model assumes preferential growth of needle ice in stone-free regions

Figure 9 Velocity vectors within a sorted circle modeled by Kessler et al. (2001), simplified from the original diagram. Movement of soil is driven by differential frost heave. during each freezing cycle and calculates the trajectory of iterative clast movements along fall lines determined partly by slope gradient and partly by the location of unfrozen soil domains. They showed that random spatial variations in clast concentration evolve initially into irregular stripes of alternating high and low clast concentration and ultimately into a stable, regularly spaced stripe pattern that is related, as in the field (Figures 4 and 11) to clast size. They also reported that the model generates sorted circles and nets where the surface slope is zero.

Although the development of shallow small-scale sorted patterns by needle-ice growth and differential frost heave is supported by both numerical modeling and observational evidence, the development of sorted patterns >1 m wide by differential frost heave operating alone is less certain. Measurements of soil movements on and within large sorted circles developed above permafrost (Hallet, 1998; Washburn, 1989) indicate the existence of long-term soil circulation with slow ($\sim 10 \text{ mm a}^{-1}$) upwelling of soil at the center of fine cells, radial movement of surface and near-surface soil toward the margins of fine cells, and net subsidence of sediment at their periphery, implying deep-seated return movement of soil toward cell centers at depth. Hallet (1998) noted that differential frost heave produces large seasonal soil displacements, but these are largely compensated by thaw settlement: it is a small annual residual displacement of sediment that contributes to long-term soil circulation. Whether such residual displacement is achieved by differential frost heave alone or depends, in part, on buoyancy forces in thawing soil (see below) is more contentious.

Figure 11 Miniature sorted stripes developed on basalt regolith at 700 m, Faroe Islands.

An important contribution to this debate has been made by Kessler and Werner (2003), who developed a numerical model capable of simulating development of all common forms of periglacial sorted patterned ground. Their model is based on the interaction between two feedback mechanisms: first, the development of inclined freezing planes, with resultant textural segregation between soil-rich and clast-rich domains, as proposed by Kessler et al. (2001); and second, lateral squeezing of clast domains during seasonal freezing and expansion of soil-rich domains. Squeezing and confinement of clast domains are assumed to drive clast movement along the axes of coarse borders, producing clast-dominated margins of regular thickness and width. These two feedback mechanisms were used to drive clast displacements over repeated iterations. As three boundary conditions (clast concentration, slope gradient, and degree of lateral confinement) were varied within the iterative procedure, different forms of sorted patterned ground evolved spontaneously. Decreases in stone concentration produced a transition from sorted circles to nets and ultimately to stone islands (stone pits); increasing slope produced sorted stripes; and stone islands proved transitional to stone polygons with increased lateral confinement (decreased soil compressibility). This model represents a remarkable

advance in understanding how sorted patterns might evolve and self-regulate their form and dimensions under a set of simplifying assumptions, but it may not incorporate the full range of processes involved.

Soil circulation

The theory that sorted patterns may be generated by buoyancy-driven convection cells operating within thawing soils also has a long history and received support in a study by Hallet and Prestrud (1986) of the dynamics of large-scale (3–6 m wide) sorted circles developed in a 1.0–1.5-m-thick active layer in Spitsbergen. Hallet and Prestrud inferred from the updoming of the fine cell centers and subsidence at the fine cell margins that the sorted circles had originated by free convection (circulatory motion caused by the buoyant rise of low-density fluid and the corresponding descent of denser fluid), arguing that the characteristics of sediment movement within the circles could be explained by the establishment of a double circulation cell in the fine domain of each circle (Figure 12(a)). They attributed such soil circulation to a decrease in soil bulk density with depth during seasonal thaw of ice-rich soil, though they stressed that convective soil movement would occur intermittently during thaw (i.e., not simultaneously throughout

Figure 12 (a) Model of sediment displacements within sorted circles proposed by Hallet and Prestrud (1986). (b) Model of free convection of porewater during active layer thawing, with resultant development of corrugations in the permafrost table. Based on Krantz WB (1990) Self-organization manifest as patterned ground in recurrently frozen soils. *Earth Science Reviews* 29: 117–130. ©1990 Elsevier Science Ltd. Reproduced with permission.

the full depth of thawed soil) and would be superimposed on cyclic soil displacement due to seasonal freezing and thawing.

Subsequent theoretical analysis by [Hallet and Waddington \(1992\)](#) of thaw consolidation in an ice-rich active layer showed that though the density profile in fine-grained soil above the thaw front may be gravitationally unstable for much of the thaw season, the buoyancy forces generated by density inversion during thaw are insufficient to drive wholesale soil circulation and thus insufficient to initiate lateral sorting. However, their analysis also indicated that buoyant soil generated seasonally at the base of the active layer tends to rise diapirically into the overlying sediment. In preexisting large-scale sorted circles, this may explain evidence for upwelling soil at the centers of fine cells ([Hallet, 1998](#)). They also showed that buoyancy-driven diapirism is likely to be enhanced (1) by a high concentration of ice lenses (due to 'two-sided' freezeback above cold permafrost) at the base of the active layer (cf. [Swanson et al., 1999](#)) and (2) in stratified soils with low-permeability basal layers. It is therefore possible that though buoyancy-driven soil circulation does not drive pattern initiation, it may produce incremental, long-term soil displacements that account, at least in part, for evidence of circulatory soil movements within existing sorted circles, nets, polygons, and stripes developed above permafrost.

Free convection of porewater

An alternative model for the initiation, spacing, and self-regulation of sorted patterns is based on density-driven movements of porewater rather than soil ([Krantz, 1990](#)). Liquid water increases slightly in density as its temperature rises from 0 to 4 °C; during thaw of frozen soil, meltwater at the thaw plane (at 0 °C) is therefore slightly less dense than overlying soil porewater. This model invokes establishment of convection cells during thaw, with descending plumes of relatively dense warm water and ascending plumes of cooler, less dense water. Downflow of warmer water is envisaged as enhancing thaw at the base of the active layer, so that a pattern of alternating peaks and troughs develops at the permafrost table ([Figure 12\(b\)](#)). Although this model predicts pattern width-depth ratios that are consistent with field observations, the link between the postulated development of subsurface corrugations in frozen substrate and that of sorted patterns at the surface has not been established. Moreover, density differences between water at 4 °C and water at 0 °C are very small and produce buoyancy effects two orders of magnitude less than those associated with density inversion in thawing soils ([Hallet and Waddington, 1992](#)). It is questionable whether they are sufficient to drive convective movement of porewater except possibly in very permeable soils.

Synthesis

As outlined earlier, theoretical considerations favor differential frost heave rather than buoyancy-driven soil circulation as the driving mechanism for the initiation of sorted patterned ground. Numerical modeling also suggests that differential frost heave may evolve from uniform one-dimensional frost heave without the need to invoke desiccation cracking, frost cracking, or lateral or vertical variations in the frost-susceptibility of soils, though such preconditions may influence the initial loci of differential frost heave and determine initial pattern spacing. It is widely

accepted that small-scale decimetric patterns can develop in areas of shallow ground freezing as a result of differential frost heave and/or needle-ice growth, with feedback-driven self-regulation producing regular spacing in sorted patterns ([Werner and Hallet, 1993](#)). Differential frost heave may also drive circulatory soil and clast movements to produce large-scale sorted patterns ([Kessler et al., 2001](#)), but it is possible that density inversion during thaw may cause buoyancy-induced soil circulation within such larger patterns.

Environmental Significance of Sorted Patterned Ground

Small-scale sorted patterns produced by differential frost heave or needle-ice growth are known to form as a consequence of shallow (often nocturnal) soil freezing and are therefore of little consequence for retrodiction of former periglacial conditions. Larger forms are diagnostic of deep annual ground freezing and thawing, and [Goldthwait \(1976\)](#) regarded sorted patterns >2 m wide as indicative of permafrost. Theoretically, however, there is no reason why large-scale sorted patterns produced by differential frost sorting cannot occur in areas of deep (>1 m) seasonal ground freezing in the absence of permafrost, provided that the soil contains abundant moisture during freezeback; the main role played by permafrost in promoting differential frost heave is that it impedes downwards movement of soil water. Reviewing the limited climatic data on the conditions under which active large-scale sorted patterns occur, [Grab \(2002\)](#) noted that all sites with active sorted patterns >1 m wide are associated with at least localized permafrost, and suggested that patterns >0.8 m wide occur where mean annual air temperature is –1.6 °C or less. Given the paucity of relevant data, this estimate must be regarded as provisional. There are, moreover, records of active sorted circles and nets exceeding 1–2 m in width in nonpermafrost areas where edaphic, hydrological, or microclimatic conditions are particularly favorable for patterned ground development, such as areas of seasonal waterlogging or glacier margins. Large-scale relict sorted patterns can be used as indicative of former permafrost or deep seasonal freezing if such circumstances can be ruled out.

Nonsorted Patterned Ground

Unlike the various forms of periglacial sorted patterns, all of which have genetic affinities, nonsorted patterns are more diverse in character and in some cases genetically distinct. Some of the most commonly occurring types are considered in the next section.

Ice-Wedge Polygons

The origin and significance of ice-wedge polygons are dealt with in detail in the article on ice wedges and ice-wedge casts, so these features are described only briefly here.

Ice wedges take the form of vertical dykes, V-shaped in cross-section, that penetrate downward into permafrost from the base of the active layer. They are initiated by thermal contraction cracking of near-surface permafrost during rapid winter cooling. Meltwater penetrating such cracks refreezes to

form vertical ice veins. Subsequent thermal contraction reopens cracks along the network of ice veins, so that ice wedges thicken incrementally with each successive episode of contraction cracking and associated meltwater refreezing. In some circumstances, open thermal contraction cracks fill with sediment rather than ice, and the resulting structures are termed primary soil wedges or primary sand wedges, depending on the nature of the infill.

The surface expression of ice wedges, primary soil wedges, and sand wedges is a polygonal network of troughs at the ground surface. Such networks, referred to collectively as frost polygons or frost-crack polygons, define two main types of pattern: low-center polygons, where polygon centers are depressed relative to ridges on either side of the ice-wedge troughs, and high-center polygons, which rise above the troughs as gentle domes. Orthogonal and hexagonal patterns are most common, though pentagonal and irregular forms also occur. Polygon diameters generally range from 5 to 50 m, and larger polygons may be subdivided by a smaller set. Relict frost polygons of late Pleistocene age often show up as crop marks on aerial photographs. Because active ice-wedge polygons are associated with continuous permafrost and severe winter cooling, relict forms indicate similar conditions in the past, though it is often difficult to establish the age of such relict features and their precise implications in terms of former air temperature regime (Murton and Kolstrup, 2003).

Vegetation-Defined Nonsorted Circles (Frost Boils) and Stripes

Nonsorted circles (circular patches of bare or sparsely vegetated soil surrounded by vegetation cover) are widespread in arctic permafrost environments, particularly well-vegetated mid- and low-arctic areas (Walker et al., 2004). Such circles are commonly termed frost boils or mud boils, are usually 0.5–3.0 m in diameter, and occur in isolation, in irregular clusters or as regularly spaced patterns (Figure 13). On gentle to moderate slopes, the equivalent landforms are nonsorted stripes consisting of alternating bands of vegetated and bare soil

Figure 13 Vegetation-defined nonsorted circles (frost boils) on Howe Island, Alaska, in summer. Unvegetated cells of mineral soil are 1–2 m in diameter and slightly domed. Photograph by Anja Kade.

aligned downslope. In winter, nonsorted circles tend to be frost heaved above the level of surrounding vegetated ground (Kade and Walker, 2008; Nicolsky et al., 2008), but in summer, they characteristically form gentle domes. The permafrost table under such nonsorted circles forms a saucer-shaped depression as a result of greater depths of thaw under unvegetated ground. Excavation of some frost boils has revealed diapiric structures indicative of injection of soil from near the permafrost table into overlying layers, and freshly exposed soil at the centers of some circles also suggests injection from below.

Peterson and Krantz (2003) developed a numerical model of nonsorted circle initiation through spontaneous generation of differential frost heave: an initial perturbation in the freezing soil results in conduction of heat from crest regions to adjacent troughs, increasing frost heave under crests and, thus, the amplitude of the perturbation, and driving water movement from troughs to feed ice-lens growth under crests. They employed linear stability analysis to predict the limiting conditions (soil texture and permeability, unfrozen moisture content and overburden pressure) under which differential frost heave occurs, and the characteristic spacing of resultant patterns. In a later paper, Peterson and Krantz (2008) also addressed the subsequent development of nonsorted circles, taking into account the insulating effects of vegetation cover in intercircle areas. They showed that the evolution of differential frost heave throughout the freezing of the active layer leads to the selection of a preferred wavelength that dictates pattern size so that the microtopography of the ground surface evolves away from the initial random configuration of crests and troughs toward a more regular pattern spacing. Peterson (2011) showed that the characteristic size and spacing of emerging nonsorted circles is positively related to active-layer depth, but is also affected by snow depth during ground freezing. Interestingly, the model developed by Peterson and Krantz (2008) suggests that permafrost is not a prerequisite for frost-boil development, provided that sufficient moisture is available; as with large-scale sorted patterns, the main effect of permafrost is to provide an impermeable substrate, so that soil water is abundant during freezing. A different modeling approach employed by Nicolsky et al. (2008) to describe soil and water movement within extant nonsorted circles emphasized the importance of waterlogged conditions and the role of nonuniform vegetation cover in initiating and maintaining differential frost heave, with movement of both water and soil toward the locus of ice-lens formation under bare or thinly vegetated circle centers (Figure 14). The importance of vegetation cover in moderating differential frost heave of nonsorted circles has been demonstrated by Kade and Walker (2008), who showed that removal of vegetation from circle centers resulted in a 6% increase in active-layer depth and a 26% increase in frost heave, whereas the addition of a 10-cm-thick moss layer to circle centers resulted in a 15% reduction in active-layer depth and a 52% decrease in frost heave.

Although differential frost heave appears to offer an adequate explanation for circle initiation (Peterson, 2011; Peterson and Krantz, 2003), evolution (Peterson and Krantz, 2008), and maintenance (Daanen et al., 2008; Nicolsky et al., 2008), the evidence for diapiric upward movement in some frost boils suggests that thaw-related soil displacements may also contribute to the development of nonsorted circles. Mackay

Figure 14 Physical processes taking place within a vegetation-defined nonsorted circle (frost boil) during autumn freezeback. (1980) proposed that, during thaw, low-density soil with high water content rises upward through overlying soil layers in the center of frost boils, being replaced by gravity-induced soil movement down the sides of the underlying saucer-shaped depression in the permafrost table, and thus driving circular movement of soil upward at circle centers and downward at circle margins. The feasibility of soil diapirism has been established by [Swanson et al. \(1999\)](#), who showed that thawed soils near the permafrost table have a bulk density up to 800 kg m^{-3} less than that of overlying dry soil. Diapiric movements of saturated soil are most likely to occur in areas of cold permafrost where upward freezing from the permafrost table in winter results in ice-rich soil at the base of the active layer, producing excess water content in this zone during thaw. It is not known whether diapiric movements of wet soil during thaw operate independently of differential frost heave to initiate frost boils through extrusion of soil at the surface, but the emergence of frost-susceptible soil at the surface is likely to result in differential frost heave, so both processes act synergistically to expand the area of the fine domain.

Earth Hummocks

A widespread phenomenon in arctic lowlands is nonsorted patterned ground consisting of roughly circular dome-shaped earth hummocks. These features are typically 0.2–0.6 m high, 0.5–2.0 m wide, and separated by a network of narrow troughs and depressions ([Figure 15](#)). Similar features occur in permafrost-free periglacial environments such as alpine plateaus, and in maritime periglacial environments such as Iceland, where they are referred to by the collective term *thúfur* ([Figure 16](#)) and are known to form on disturbed ground within a few years or decades. Earth hummocks usually occur as closely

Figure 15 Earth hummocks developed above permafrost, Ellesmere Island, arctic Canada.

spaced assemblages on flat or gently sloping terrain of frost-susceptible soils containing few or no stones, in areas of tundra, grassland, or open subarctic woodland. Both hummocks and the intervening troughs are usually completely vegetated, apart from the localized erosion of hummock crests. On gentle slopes, earth hummocks are sometimes elongate downslope, and where gradient exceeds about 6° earth hummocks sometimes grade into nonsorted stripes (relief stripes) that form a ridge-and-furrow pattern on slopes ([Ballantyne and Harris, 1994; Nicholson, 1976; Figure 17](#)). In high-arctic permafrost environments, however, hummocky microforms referred to as *slope hummocks* occur on slopes of $6\text{--}27^\circ$ ([Figure 18](#)). Such slope hummocks resemble the earth hummocks found on more level ground, but have a distinctive origin ([Lewkowicz, 2011; see below](#)).

Figure 16 Thúfur field developed on permafrost-free terrain, northern Iceland.

Figure 17 Nonsorted 'relief stripes' at 900 m on Seana Braigh, northern Scotland. These stripes are inactive under present conditions.

Figure 18 Section excavated through a slope hummock on a slope of 8°, Ellesmere Island, Canadian Arctic Archipelago. Burial of organic soil at the downslope edge of the hummock suggests rotation of the hummock as it moved downslope over a deforming substrate during thaw of ice-rich soil (gelifluction).

Sections excavated through earth hummocks usually reveal disruption and deformation of underlying sediments, often in the form of updomed soil horizons and/or diapiric intrusions of fine-grained, sometimes organic-rich soil, though hummock

stratigraphy may be complex (Van Vliet-Lanoë et al., 1998). In permafrost areas, the permafrost table underlying hummocks takes the form of bowl-shaped depressions. These reflect slower summer thaw under interhummock troughs, which retain snow longer and often contain a thicker insulating cover of vegetation and organic-rich soil than hummock crests (Kokelj et al., 2007).

Although it is widely accepted that earth hummocks owe their development to soil displacement induced by recurrent freezing and thawing of the ground, there are several theories as to how they are initiated (Grab, 2005). A long-held view is that hummock growth in permafrost areas is generated by upward displacement of soil due to generation of cryostatic (effectively hydrostatic) pressure in confined pockets of saturated, unfrozen soil during freezeback, an effect that is likely to be self-sustaining once surface microrelief has formed (Nicholson, 1976). Mackay (1980), however, pointed out that pockets of unfrozen soil are likely to be desiccated as a result of water movement to the freezing plane to feed growing ice lenses. Mackay proposed an alternative equilibrium model for hummocks that involves radial displacement of sediment down the flanks of hummocks during thaw, inward movement of sediment toward the floors of bowl-shaped depressions in the permafrost table, and buoyancy-driven diapiric rise of mud toward the hummock crest toward the end of the thaw season. This circulatory motion is initiated by the development of bowl-shaped depressions in the permafrost table, which Mackay attributed to the formation of unvegetated areas ('mud patches') under which seasonal thawing is deeper.

Differential frost heave offers an alternative solution to the problem of hummock initiation. Lewis et al. (1993) calculated that differential frost heave may generate a characteristic longitudinal wavelength compatible with hummock dimensions, and the differential frost heave model of Peterson and Krantz (2003) may also apply to hummock initiation. Once a pattern of crest and depressions has become established through differential frost heave, preferential vegetation growth and organic soil formation in depressions may result in deeper frost penetration under crests than troughs, and consequent formation of bowl-shaped depressions in the permafrost table. Whether subsequent hummock evolution reflects buoyancy-driven soil circulation, as advocated by Mackay (1980), or gradual ice enrichment beneath an aggrading permafrost table, as proposed by Kokelj et al. (2007), is unclear. Both appear plausible, though diapiric structures in some hummocks favor the former.

Models that depend on the establishment of depressions in the permafrost table, however, cannot explain the formation of thúfur in permafrost-free areas. These may be initiated by differential frost heave, as advocated by Lewis et al. (1993), but the evolution of mature hummocks from differentially heaved crests and depressions has not been demonstrated. Van Vliet-Lanoë et al. (1998) have suggested that hummocks in nonpermafrost areas develop through differential frost penetration initiated by desiccation cracking, with subsequent upward injection of subsurface sediment along dilation cracks during thaw. At present, there is no single model that appears to account for hummock formation in both permafrost and nonpermafrost environments. Differential frost heave is probably widely responsible for hummock initiation, but

the subsequent evolution of earth hummocks in different environments may encompass different mechanisms, potentially including differential frost heave, buoyancy-driven soil diapirism, soil uplift above aggrading ice-rich permafrost, and dilation cracking and soil injection. The development of relief stripes on slopes seems to imply an overall cellular circulation of soil, on which gradient imposes a gravity-induced downslope vector of soil movement, but not all earth hummocks grade into relief stripes as slope increases.

The slope hummocks that occupy gentle to moderate slopes in high-arctic permafrost environments appear to develop in a distinctive way that is largely independent of the processes outlined earlier. Lewkowicz (2011) argues that slope hummocks evolve through accumulation of niveo-eolian sediment on hummock crests, removal of sediment between hummocks by slopewash, and slow downslope movement of hummocks by solifluction. Some slope hummocks even exhibit structures that indicate rotation of individual hummocks as they move downslope over a deforming substrate (Figure 18).

Because earth hummocks form in nonpermafrost environments, relict earth hummocks such as those on British mountains (Ballantyne and Harris, 1994) are not necessarily diagnostic of former permafrost. There is some indication, however, that the formation of *thúfur* in Iceland may be related to Holocene climatic shifts: Van Vliet-Lanoë et al. (1998) have employed tephrostratigraphy to relate periods of late Holocene hummock growth to periods of climatic deterioration.

Conclusion

Explanation of sorted and nonsorted periglacial patterned ground has traditionally been based on the concept of multiple origins. Recent numerical models complemented by field and laboratory experiments suggest that most if not all patterns apart from frost polygons are initiated by differential frost heave, either generated spontaneously from one-dimensional frost heave or by some perturbation such as ground cracking. Differing initial boundary conditions (particularly vegetation cover) probably explain the contrast between sorted and nonsorted forms. The subsequent evolution of some patterned ground forms, however, may involve additional mechanisms, of which buoyancy-induced soil movement is the most important. Understanding of the full range of processes operating and their environmental controls is a research priority if relict patterned ground forms are to be employed in Quaternary environmental reconstruction.

Permafrost

C R Burn, Carleton University, Ottawa, ON, Canada

Introduction

Permafrost is the ground that remains at or below 0 °C for 2 years or more. Permafrost forms a layer, centimeters to kilometers thick, sandwiched between a seasonally thawed active layer at the surface of the ground, and unfrozen ground at depth. The thickest permafrost formed during the Pleistocene in unglaciated Siberia, and is over 1500 m deep (French, 2007). Permafrost in Alaska and western Arctic Canada is up to about 600 m thick, again due to permafrost aggradation during the Pleistocene under subaerial conditions. The persistence of permafrost increases with its thickness so that deep permafrost may not only take many millennia to form, but its degradation would occur over similar timescales.

Permafrost is a product of climate. At continental scale, the two most important controlling variables are air temperature and winter snowfall. As a result, permafrost is found at relatively high latitudes and at high altitudes (Brown et al., 1997). In western North America, permafrost is found at more southerly latitudes than in western Eurasia because the Cordillera blocks weather systems originating in the Pacific, creating a continental climate inland. This climate not only provides low winter temperatures, but also a rain shadow, leading to relatively low snowfall, and hence relatively little insulation for the ground from the frigid conditions. Permafrost is widespread in Alaska and Canada's Yukon Territory, but there is little permafrost in northwest Russia. The extent of permafrost in the Yukon increased during the Quaternary interglacials, as the St. Elias Mountains were uplifted, and the climatic effectiveness of this coastal barrier increased (Burn, 1994).

The top of permafrost is characteristically ice rich, so that if the active layer deepens and permafrost thaws, the surface of the ground may become unstable. Subsidence is common in flat terrain after disturbance, but may not be spatially uniform, and water may accumulate in the resulting depressions. These ponds perpetuate the thermal disturbance, and grow into water bodies known as thermokarst, or thaw, lakes. Lakes are common in permafrost terrain because the frozen ground around and beneath them inhibits seepage. On hillslopes, thawing of the ice-rich ground at the top of permafrost may lead to landslides, due to reduced friction on the surface of melting ice lenses, and loss of shear strength following an increase in pore-water pressure (French, 2007). The principal natural disturbance currently encountered is forest fire, but most infrastructure construction also leads to active-layer deepening, and therefore requires careful management and application of special techniques to prevent ground instability.

Thermal Regime

Figure 1 illustrates the thermal regime of permafrost. The two principal features are an envelope of ground temperature near the surface and an increase in ground temperature with depth.

The mean annual temperature at the top of permafrost, T_p , is one of three variables that governs the thickness of permafrost, z , which also depends on the geothermal flux, G , and the thermal conductivity of the frozen ground, λ (Williams and Smith, 1989). G is related to z by:

$$G = \lambda T_p / z \quad [1]$$

Of these variables, the geothermal flux is spatially the most constant, ranging in North America between 0.05 and 0.2 W m⁻², through the stable craton of the Canadian Shield to the tectonically active terrain of the Cordillera. The thermal properties vary with water and ice content. Air, water, and ice have λ of 0.022, 0.56, and 2.2 W m⁻¹ °C⁻¹, respectively, and specific heat capacities, c , of 0.86, 4200, and 1900 kJ m⁻³ °C⁻¹, respectively. Mineral materials have λ of about 2.0 W m⁻¹ °C⁻¹ (except for quartz, 8.0 W m⁻¹ °C⁻¹), and c of about 2200 kJ m⁻³ °C⁻¹ (Burn, 2004).

The two sides of the ground temperature envelope represent the annual minimum and maximum temperatures in the ground. These values do not occur simultaneously with depth, but are reached progressively later from the surface downwards. In practical terms, the depth at which the difference between annual minimum and maximum temperatures is less than 0.1 °C represents the depth of zero annual amplitude, z_0 , and the temperature at this depth, T_g , is the mean annual ground temperature. In most locations, z_0 is at a depth of 15–25 m. The variation in z_0 depends primarily on the thermal diffusivity, λ/c . In bedrock and sand, λ/c is relatively high, and z_0 relatively large, but in peat and where the active layer is wet, the temperature envelope attenuates near the surface, and z_0 is relatively small. In thin permafrost, z_0 may be at the base of the perennially frozen ground.

T_p depends on the mean annual ground surface temperature, T_s , and the seasonal change in λ within the active layer due to freezing and thawing. The difference between T_s and T_p is the thermal offset (Romanovsky and Osterkamp, 1995). The thermal offset increases with water (ice) content in the active layer, and is therefore greatest in saturated peat, which has a high porosity.

Aggradation and Degradation

Freezing and thawing of the ground occur in response to the seasonal variation in climate at the ground surface. Permafrost forms where seasonal frost penetration exceeds thawing during the following summer. The thermal offset is a product of the asymmetry in seasonal values of λ , and is critical in permafrost development at the limit of perennially frozen ground. The principal variables governing the development of permafrost are T_p , λ , L , the latent heat of fusion of unfrozen ground, and t , the time since initiation of freezing. The depth of aggrading permafrost, z , is related to these variables by (Williams and Smith, 1989):

Figure 1 Thermal regime of permafrost.

$$z = \sqrt{(2\lambda T_p t / L)} \quad [2]$$

where λ is the value for frozen ground. Equation [2] is the Stefan solution, a model that assumes freezing follows a step change in surface temperature, and that the ground is uniformly at 0 °C before freezing begins. The former assumption is a valid approximation of conditions following drainage of lakes in permafrost regions, where permafrost aggrades into the unfrozen lake bottom. The latter is also valid, because c is two orders of magnitude less than L , so the heat budget is dominated by freezing of water, not cooling of the ground. Equation [2] is useful for estimating the time required to form deep permafrost. For example, permafrost thickness varies in association with the glacial limits near the western Arctic coast of Canada over distances of less than 50 km. At unglaciated locations, the thickness is over 500 m, but at glaciated sites the thickness is 300 m or less. Significant permafrost did not develop beneath glacial ice in this area, and these depths represent the combination of differences in time and surface temperature history for the area.

The Stefan solution is also valid for determination of the rate of permafrost thaw following surface disturbance, but in this case λ is for thawed ground, and T_p is the new ground temperature above 0 °C. An important aspect of this model is the relation between depth of thaw and square root of time. This implies that even relatively thin ice-rich permafrost, on the order of 10 m, requires centuries to degrade following the perturbations to ground temperature accompanying natural disturbances (Burn, 1998). There are no landscape-scale data to test the model for permafrost degradation over Quaternary time, but as for aggradation, the model has been verified for natural disturbances such as forest fires, thaw slumps, and thaw lakes. In the case of developing thaw lakes, horizontal expansion may be equivalent to thaw deepening, where t is 1 year.

Upward thawing of permafrost from its base is a very slow process, because of the low geothermal flux and high L . The rates of thaw are 0.5–2.0 cm year⁻¹, except where additional heat is supplied by groundwater convection.

Ground Surface Temperature

T_s is a function of the surface energy balance, so while it is broadly governed by the climate, at local scale it is a function of aspect, shade, ground surface wetness, and the winter snow cover (Williams and Smith, 1989). Shade and soil moisture reduce the ground temperature in summer by lowering incident radiation and promoting evaporation, respectively. Aspect is important in mountainous areas, for in the Northern Hemisphere, south-facing slopes receive critically more radiation in spring and autumn, keeping these surfaces above 0 °C for longer than slopes with other aspects. Snow cover provides insulation at the ground surface in winter, trapping the ground heat flux and raising surface temperatures. In combination, these factors are responsible for a variation in T_s of about 5 °C in any locality. The influence of the snow cover is responsible for raising T_s above the mean annual air temperature, in general by about 3 °C, but in places by as much as 10 °C (Smith et al., 1998). As a result of such variation, permafrost is spatially discontinuous through a considerable extent of its distribution, for in places, T_g may locally vary above and below 0 °C.

The importance of snow cover is well demonstrated by data collected from peatlands in Canada's western Arctic at Inuvik, south of treeline, and Parson's Lake, in the tundra, 60 km north of Inuvik, during 1993–94. T_s at Inuvik was approximately –1.7 °C, while at Parson's Lake, T_s was –5.5 °C (Smith et al., 1998). The snow cover at Inuvik is commonly 50 cm deep by the end of March, with a density of about 0.2 g cm⁻³, while at Parson's Lake there is about half the snow depth, and the snow pack has twice the density, raising its λ .

The relation between air and ground surface temperature at a site may be obtained through detailed flux measurement and determination of the surface energy balance. Such an approach is inappropriate for many practical purposes and for predicting permafrost conditions over large areas. Instead, the relation may be summarized through the n -factor, or ratio of air-to-ground surface temperature. The n -factors for a site are determined for the freezing, n_f , and thawing, n_t , seasons. These indices vary with surface and subsurface characteristics. In winter, n_f depends on snow depth, but also the amount of unfrozen ground in the soil profile. Where the active layer is deep or wet, release of latent heat during soil freezing maintains a high T_s , and reduces n_f (Karunaratne and Burn, 2004). In summer, n_t depends on the rate of thawing, because energy initially entering the soil is used to melt ice rather than warm the ground. In the latter half of summer, air and ground surface temperatures are almost equal. For sites in the boreal forest, values between 0.1 and 0.5 have been measured for n_f , and between 0.6 and 1.1 for n_t . The values may be substantially higher for artificial surfaces.

Forest fires cause the most widespread natural disturbances to surface conditions in permafrost regions. These fires are not often extinguished rapidly because of their remote locations. Permafrost is rarely affected by the fire itself, but degrades

following the change in surface conditions (Burn, 1998). In particular, ground temperatures increase because of loss of the soil's organic layer and the shade of trees, drying of the soil surface, and the increase in snow accumulation following destruction of the canopy. As a result, landslides are common in sloping terrain following fires.

Distribution

At the continental scale, latitudinal permafrost is mapped according to its extent beneath the land surface (Figure 2). Continuous permafrost is defined as regions where 90% or more of the land surface is underlain by perennially frozen ground. Discontinuous permafrost is divided into categories of widespread, sporadic, and isolated patches of permafrost, where, respectively, 90–50%, 50–10% and less than 10% of the surface is underlain by permafrost. In addition, subsea permafrost occurs in the continental shelves of the Arctic Ocean at locations that were dry land during glacial periods, when sea level was lower (Brown et al., 1997; for instance, the Bering Land Bridge). Alpine permafrost is classified at high elevations in areas where latitudinal permafrost is not prevalent, such as

the extensive permafrost of the Tibetan plateau. Lake and river bottoms are not included in the measure, because permafrost is normally absent immediately beneath water bodies that do not freeze through. Unfrozen ground surrounded by permafrost, such as beneath lakes and rivers, is known as talik.

The distribution of permafrost is fundamentally a function of climate, but is modified by surface characteristics. Near its limit, permafrost is characteristically present in peatlands, because the thermal offset induces mean ground temperatures below 0 °C, even though the surface conditions may be several degrees Celsius higher (Smith and Riseborough, 2002). The continental boundary between discontinuous and continuous permafrost follows treeline, as a result of forest and shrub vegetation enhancing the snow pack by reducing ground-level wind speed and, hence, drifting. In the Northern Hemisphere, the southern limit of continuous permafrost has been considered to correspond with a mean annual air temperature of –8 °C, or T_g of –5 °C. Permafrost in this region is continuous in both space and time, because a considerable climate change is required to degrade it. Even submersion by rising sea level has not yet led to the eradication of the continuous permafrost established during the Pleistocene in the coastal shelves of the Arctic Ocean.

Figure 2 Distribution of permafrost in the Northern Hemisphere. Ground Ice

The geotechnical significance of permafrost is derived from the presence of excess ice, that is ice content greater than the saturation water content. Excess ice occurs in the ground following burial of surface ice, such as river, lake or glacial ice, or it may form in the ground itself (French, 2007). There has been considerable discussion surrounding the origin of extensive tabular beds of massive ice, which are bodies of almost pure ice found near the western Arctic coast of Canada (Figure 3) and near the Siberian coast. Within the glacial limits, some glacier ice is preserved (Murton, 2009), but other massive ice formed within sediments. There are two principal processes responsible for the growth of ice in sediments, and these depend on the particle-size composition of the materials.

In coarse-grained sediment, such as sand, freezing of saturated ground is accompanied by expulsion of water, as the specific volume of ice is greater than that of water, and so the porosity is exceeded. In confined systems, the expelled water raises local water pressure, and so there is potential for water to be injected into cracks in the frozen ground, or to lift the ground and form a pressurized, subterranean pool (Mackay, 1998). The water may then freeze in place to form massive ice. This is the mechanism responsible for the development of pingos in drained lake basins, and for some frost blisters, or ice-cored mounds, within the active layer.

In silts and clays, however, films of adsorbed water remain unfrozen at the surface of soil particles, and during freezing these conduct water along soil moisture potential gradients into freezing soil (Williams and Smith, 1989). The potential gradient is proportional to the temperature gradient, but a suction of $1.2 \text{ MPa } ^\circ\text{C}^{-1}$ develops, and over time moves water through the soil even though the hydraulic conductivity is relatively low. As the water moves into freezing ground the volume rises above saturation, and soil particles are pushed apart to form layers of pure ice (Figure 4). The process is called ice segregation. Lenses of segregated ice are common in most freezing soils, and are responsible for the uplift, or frost heave, of the ground. Large massive-ice bodies in permafrost have been formed by a combination of freezing in coarse sediments, which provided a ready supply of water under pressure, and

overlying silty clay, in which segregation led to development of large ice lenses (Figure 3; Mackay and Dallimore, 1992).

Segregated ice is almost ubiquitous at the top of permafrost in unconsolidated sediments and some bedrock. This ice-rich zone is commonly 0.5–1.0 m thick, and contains ice lenses that have formed with water drawn downward into permafrost from the base of the active layer at the end of summer and in early autumn. This ice-rich layer and the occurrence of ice wedges at the base of the active layer combine to make permafrost terrain sensitive to disturbance.

Ice Wedges

Ice wedges are one of the few geomorphic features of diagnostic of permafrost (Mackay, 2000). These wedge-shaped masses of relatively pure ice form at the base of the active layer following repeated cracking of the ground due to thermal contraction in winter (Figure 5). The thermal contraction cracks are infiltrated by snowmelt, which freezes to form relatively weak vertical planes of ice in the near surface that become loci for cracking in subsequent winters. In dry environments, or where sand is abundant, the cracks may be infilled with eolian deposits to form sand wedges or composite sand and ice wedges (French, 2007). After repetition of the cracking and infilling over many winters, the vertical veins of ice grade into wedge-shaped structures because the cracks vary annually in depth. The frequency of crack penetration, and of the depth of infiltration, declines below the active layer. The addition of volume to the permafrost through the growth of wedges leads to deformation of adjacent stratigraphy, so that bedding is upturned next to wedges, and characteristically two ridges form at the surface on either side of the wedge. The wedge underlies a central trough, formed as the ground separates above the growing wedge. The troughs intersect to create a network of irregular, four- to seven-sided polygons, which are common in surficial sediments throughout continuous permafrost (Figure 6). If permafrost degrades, the primary structures of sand wedges may be preserved in stratigraphy, but ice wedges melt and may be replaced by casts formed from material that infills the void.

Figure 5 Ice wedge exposed near Tuktoyaktuk, Northwest Territories, Canada. Photograph taken in April 1987 by C.R. Burn.

Three types of ice wedge are recognized from different sedimentary environments (Mackay, 1990). Epigenetic wedges form under a stable surface, syngenetic wedges in surfaces of deposition, and antisynthetic, or hillslope ice wedges, where the surface is eroding. Epigenetic wedges are V-shaped, with flat tops that have been truncated at the base of the active layer. Since the thermal contraction crack penetrates downwards into the ground from near the top of permafrost, syngenetic wedges are characteristically long and thin, for the apex of the crack migrates upwards with the point of crack initiation, as the surface is raised.

The size of an ice wedge is not a reliable guide to its age, as the rate of growth of wedges varies with time. Initially, growth is rapid, but as the ridges on each side of the wedge grow and trap snow, the drifts reduce the thermal stress. Networks of thermal contraction cracks have been presumed to become denser as the climate becomes colder and conditions for cracking improve. However, field observations indicate that wedges cease to crack frequently as they age, so secondary wedges may develop to divide primary polygons and relieve thermal stress under constant conditions. In field stratigraphy, the size of an ice wedge also depends on its angle of exposure, for few wedges are exposed in true cross section.

Lakes

Lakes alter ground temperature substantially from patterns determined by climate (Burn, 2002). Ground beneath lakes is warmer than the surrounding permafrost because lake-bottom temperatures are at or above 0 °C throughout the year, unless the water body freezes through. In bedrock areas, many lakes occupy depressions formed by glacial erosion, but in sediments the lakes are commonly thermokarst features (Figure 7). Once a lake is established, its development continues until the ground ice surrounding the lake is exhausted, the water balance cannot sustain the lake, or it drains by thermal erosion of surrounding permafrost. Down-cutting and enlargement of a small channel through ice-rich ground is well-established as the primary mechanism of rapid lake drainage in northwest North America (Mackay, 1997).

In the boreal forest, some thaw lakes are sheltered from the wind and mixing of the water body in summer is restricted to the upper 2 m or so. In contrast, most tundra lakes, and larger lakes in the boreal forest, are well mixed in summer, and temperatures are uniform to depths of about 30 m. Many tundra lakes have well-developed littoral terraces, beneath water depths of less than 1 m, in which permafrost is

preserved, and a central pool of deeper water where the mean annual lake-bottom temperature is between 2 and 4 °C (Figure 8). Beneath the deep pool, a talik (unfrozen ground) develops whose dimensions depend on the width of the lake as well as the temperature at the lake bottom and in the surrounding permafrost. The width of the lake is the most locally variable factor, and so controls whether the talik penetrates the full thickness of permafrost or is closed beneath the lake.

The flat tundra regions of western Arctic Canada, Alaska, and Russia contain extensive areas where lakes of all sizes are oriented in a common direction, perpendicular to the prevailing winds. Several theories have been proposed to account for the consistency of orientation, but the most convincing is that in summer, when the lakes have no ice cover, the strongest winds establish a two-cell current circulation. This leads to preferential erosion at the ends of the lakes by water driven across the lake and returning around the lake shore. The mechanism has been replicated in the laboratory, and is consistent with observations from western Arctic Canada, where, within a few hundred kilometers, lake orientations vary by 90° in association with changes in wind direction.

Hillslopes

In addition to catastrophic movements on slopes induced by thawing of near-surface permafrost, slower downslope movement occurs due to ice in the ground. At the surface, the active layer commonly moves downslope relative to permafrost at the end of summer as the depth of thaw approaches the ice-rich zone at the base of the active layer. The movement, called solifluction, may be at a rate of up to a few centimeters per year. The moving soil forms lobes that spill onto flat ground in the valley floor when they reach the bottom of the slope. The heights of the solifluction lobes are about 60 cm at the foot, and they grade back into the hillslope. The front of each lobe rolls gradually over onto itself, so that vegetation is buried, and this layer is progressively older upslope (French, 2007).

Ice-rich permafrost itself deforms in response to gravity, because at ambient temperatures the ice is close to its melting point and so tends to creep. Downslope deformation of

permafrost has been measured both in massive ice and ice-rich clay in northwest Canada (Dallimore et al., 1996), and the development of rock glaciers in boulder fields with a matrix of pore ice, is also due to creep of the interstitial ice. In Alpine regions, rock glaciers are a common product of permafrost creep, but built structures may also cause such deformation because of the additional load they apply to hillslope materials.

Other Landforms

Two other sets of landforms are characteristic of permafrost terrain. If ice-rich permafrost is exposed by erosion in river banks, lake shores, or at the coast, then ablation of ground ice may initiate development of retrogressive thaw slumps. These features consist of a steep headwall of thawing permafrost, connected to the locus of erosion by a footslope of low gradient (Figure 9).

Thaw slumps are active during summer, when air temperatures are above 0 °C, and are among the most rapidly developing geomorphic features, with measured rates of headwall retreat up to 16 m year⁻¹.

Perhaps the most well-known permafrost landforms are pingos, conical hills that contain a core of ice (Mackay, 1998). The ice accumulates from water pushed into ground beneath the pingo by pressure from a hydraulic head developed down a hillslope, or due to the growth of permafrost in saturated sand. Pingos formed at the base of hillslopes are best documented from Greenland, Alaska, Yukon Territory, and Svalbard, while pingos forming from aggradation of permafrost are best known from Canada's western Arctic coastlands (Figure 10).

Permafrost and Climate Change

Since permafrost is both a function of climate and a structural component of cold-regions' terrain, its response to climate change anticipated during the twenty-first century is significant for infrastructure planning and management of natural resources. The time involved in thawing permafrost completely is great, so over the next hundred years it is unlikely there will

Figure 8 Thaw lake on Richards Island, Mackenzie delta area, western Arctic coast, Canada, showing littoral terraces surrounding a central pool. Photograph taken in August 1991 by C.R. Burn.

be widespread eradication of perennially frozen ground, except where the current thickness is only a few meters. At present, warming of polar regions is expected to be significant, but as important for permafrost is the projected increase in snow fall. Two principal effects of regional climatic warming are an increase in the temperature of permafrost, and deepening of the active layer, with associated consequences for ground stability.

The thermal response of permafrost to climate warming involves an inflection of the ground temperature profile, so that the coldest part of the ground is located progressively deeper in the profile. Curved ground temperature profiles indicating warming of permafrost since the 1850s have been obtained in northern Alaska, and indicate the response to climate warming since the Little Ice Age (Lachenbruch and Marshall, 1986). During the 2007–2009 International Polar Year, an integrated circumpolar program to determine the current temperature in permafrost reported warmer conditions than in prior assessments at almost every location (Romanovsky et al., 2010). Many of the reports contained near-surface observations only, and so the time scale of permafrost disturbance remains elusive. However, where deeper measurements have become available, the time scale of permafrost disturbance is interpreted to be similar to that in Alaska (e.g., Burn and Zhang, 2009). There has been some monitoring of near-surface permafrost in northwest North America during the last 20 years which indicates ground warming in general, but cooling at locations where snow depths have been low (Osterkamp and Romanovsky, 1999). In terms of ground temperatures, the response is most easily detectable in relatively cold permafrost, because the additional energy is used to warm the ground, while in warm permafrost much of the additional energy is consumed by the latent heat required to melt ice. As a result, the thermal response of discontinuous permafrost to climate warming is slower and more difficult to detect than the response of continuous permafrost, even though considerable thawing may be occurring.

A thicker active layer is anticipated under climate warming, because of warmer summer conditions and deeper snow cover in winter. Evidence of a regionally deeper active layer in northwest Canada is preserved in cryostratigraphy by a thaw unconformity about 1.5 m below the base of the present active layer (Burn, 1997). The deep seasonal thaw has been associated with the Holocene thermal optimum, which occurred there

9000 years ago, and a more northerly treeline because the coast was 100 km further north at the end of glaciation. The unconformity has been recognized from truncated ice wedges and a change in the form and concentration of ground ice (Figures 4 and 11). The base of the active layer has aggraded upwards from this unconformity, and considerable ice has been incorporated in the uppermost meter of permafrost. Thaw of this ground would liberate this ice, and would also make organic matter currently contained in permafrost available for decomposition by microbial processes in the active layer. It is not yet clear whether a more biologically productive boreal landscape would act as a net carbon sink, from increased vegetation growth, or a net source from decomposition of organic matter currently unavailable in permafrost (Mack et al., 2004). There is considerable research in progress on this topic, because preliminary results suggest a massive amount of carbon is stored in the upper 3 m of permafrost, on the order of 10^{15} kg, or over 100 times the world's annual industrial emissions (Kuhry et al., 2009; Tarnocai et al., 2009).

An area of particular interest with respect to carbon release from permafrost terrain concerns methane production from thermokarst lakes. Graphic demonstrations of methane bubbles caught by lake ice igniting when punctured have illustrated the contribution of this process to the carbon budget of the atmosphere (e.g., Walter et al., 2006). As a result, there is interest in whether permafrost degradation beneath thermokarst lakes will increase as climate warming accelerates. The key issues are whether the rate of lake initiation will accelerate, for which there is some evidence (Jorgenson et al., 2006), and whether the rate of lake expansion will change. There are few studies yet of the latter, but Burn and Smith (1990), in finding lake expansion was governed by the Stefan solution, noted the consistent rate of increase in lake radius, and hence an accelerating change in lake area. A complicating factor is that lake expansion may lead to lake drainage and cessation of permafrost degradation (Mackay, 1992). In summary, the evidence, particularly from Alaska, of increasing numbers of thaw lakes, supports the concern that degrading permafrost will emit increasing amounts of methane into the atmosphere.

This article is a revision of the previous edition article by C. Harris and N. Ross, volume 3, pp. 2200–2207, © 2007, Elsevier B.V.

Introduction

Frost mounds are ice-cored hills or hummocks found in areas of permafrost and/or seasonally frozen ground. They comprise pingos, palsas, lithalsas, and seasonal frost mounds and blisters. There is significant diversity in their scale, host material, mechanism of formation, ground-ice type, and origin. One process, however, is common to all frost mounds: the subsurface formation of ground ice (injection or segregation ice) generates upward forces able to heave and deform overlying frozen materials, resulting in the upward doming of the ground surface.

The collapse of frost mounds can result from mechanical processes (e.g., extension of the overburden material to expose the ice core) or climate forcing (e.g., thickening of the active layer into the ice core). Melting of an ice core over a prolonged period is liable to lead to the collapse of a frost mound. As the ice core melts out, significant sediment redistribution toward the margins of the landform can occur through mass movement and surface wash. These processes (thaw and redistribution of sediment) have the potential to generate annular ring-like ridges or ramparts surrounding central water-filled depressions. Not all frost mounds, however, generate a geomorphological signature of their demise; preservation potential is highly dependent on local factors, particularly the host material. Nevertheless, numerous examples of circular or near-circular enclosed depressions have been recognized in present-day temperate areas. Many of these landforms were initially interpreted as the remains of pingos formed during Quaternary cold periods. Wisely, however, some researchers were more cautious (Sparks et al., 1972), and many landforms once interpreted as pingo 'scars' have since been reinterpreted as the remains of other types of frost mounds (see Pissart, 2000, 2003 and references therein), or even as landforms formed by glacial processes (Iannicelli, 2003).

This article describes (i) the growth and collapse of active frost mounds in present-day periglacial environments, and (ii) Quaternary landforms ('ramparted depressions') interpreted as relict frost mounds. It focuses on those contemporary frost mounds that are likely to have a long-term geomorphological signature (i.e., pingos, mineral palsas, and lithalsas).

Modern-Day Frost Mounds

Pingos

Pingos are perennial frost mounds found in the continuous and discontinuous permafrost zones (Figures 1 and 2). They are typically produced by the injection and subsequent freezing of water within near-surface sediments or bedrock, resulting in the formation of a massive ground-ice body and the heave of overlying materials.

The injection of water into near-surface permafrost to form a pingo ice core capable of deforming units of overlying frozen sediments (often several meters thick) and dome the land surface requires high subsurface water pressures. These pressures can develop in two ways: either (i) in a closed system, as a result of water expulsion from saturated coarse-grained sediments during refreezing of a talik (a zone of unfrozen sediment within continuous permafrost); or (ii) in an open system, because of artesian water pressures within a subpermafrost aquifer (Holmes et al., 1968; Mackay, 1998; Müller, 1959). In permafrost environments, both processes lead to the upward injection and freezing of water. Pingos are categorized on the basis of their process of formation: the first type is referred to as 'closed-system pingos' (or hydrostatic pingos) and the second type as 'open-system pingos' (or hydraulic pingos). The former occur in lowland settings within the continuous permafrost zone, generally in localities where surface lake drainage has occurred, while the latter are more common in valley-bottom and footslope localities in both discontinuous and continuous permafrost.

Closed-system pingo formation

Much of our understanding of the nature and origin of closed-system pingos derives from the seminal studies of Mackay in the area northeast of the Mackenzie Delta, Canada (Mackay, 1998). Here, permafrost is developed in a thick sequence of deltaic sands, often mantled by clays and silts. In these lowland areas, surface water accumulates in summer to form pools and lakes. If the lake depth is greater than the winter ice thickness, then the lower parts of the lake will remain liquid throughout the year and the mean annual lake bottom temperature will be above zero. This will have a strong thermal influence on the underlying permafrost, and a thaw bulb or talik will develop below the lake (Figure 3).

The lakes of this region are typically impounded by perennially frozen but unconsolidated sediments. As a result, the lakes are highly susceptible to sudden drainage events generated by thermal erosion around the lake shore and by mass-wasting processes. When lakes drain, the underlying sediments are no longer insulated by the overlying water body, and so the talik begins to refreeze. Permafrost aggrades both from the surface downwards and from the lateral margins of the talik inwards (Figure 3). When the unfrozen saturated sands in the talik freeze, the 9% volume increase associated with the phase change from liquid water to ice results in expulsion of approximately 9% of the porewater ahead of the advancing freezing front. This expelled water migrates, under hydrostatic pressure, to the zone of least confining stress, usually below a residual pond within the drained lake basin (Figure 3). Freezing from the surface downwards then initiates the formation of the pingo ice core.

Figure 1 View of a closed-system pingo, Mackenzie Delta, Canada. Photograph by Charles Harris.

Figure 2 Open-system pingo, Adventdalen, Svalbard. The pingo has a height of ~30 m and a diameter of around 200 m. Photograph by Neil Ross.

If the rate at which expelled porewater accumulating beneath the bottom of the pingo ice core exceeds the downward rate of freezing of the water, then a subpingo water lens develops (Figure 3). In this instance, the hydrostatic pressure is able to support the overburden stress and cause further uplift and deformation of the overlying ice core and frozen overburden (Mackay, 1998). Monitoring of closed-system pingos indicates that high hydrostatic pressures in subpingo water lenses can mechanically fracture the overlying materials, leading to (i) rupturing of the pingo sides, (ii) high-angle faulting of overlying frozen sediments, (iii) formation of surface springs, and (iv) development of winter icings.

Closed-system pingos in northwest Canada may exceed 40 m in height, though the vast majority are <20 m high (Mackay, 1998). Basal diameters up to about 250 m have also been recognized. The diameter and plan form of closed-system pingos depend on the size and shape of the original talik, which is often circular or elliptical beneath thaw ponds, but can be markedly linear beneath elongated large water bodies, leading to the formation of linear, ridge-like pingos (Pissart and French, 1976).

Importantly, closed-system pingos have the potential to grow extremely rapidly. Data collected from a pingo in northwest Canada, which began growing soon after 1950, showed rapid initial growth that then slowed (Mackay, 1998). However, Mackay was careful to warn that generalizations on pingo

Figure 3 Formation of closed-system pingos. (a) Development of a talik beneath a thaw lake. (b) Lake drainage leading to refreezing of the talik and pore water expulsion as the permafrost table advances inwards. (c) Progressive freezing of a pressurized subpingo water lens leading to thickening of the pingo ice core and pingo growth. (d) Pingo collapse due to partial thaw of pingo ice beneath a central pond. growth rates based on this sole example were probably inappropriate. Only some of the pingos monitored in his studies showed a progressive uplift: some pingos ruptured, causing water loss from subpingo water lenses and subsequent subsidence, while others showed up-and-down oscillations (Mackay, 1998).

Open-system pingo formation

In contrast to the closed-system type, open-system pingos are most common in areas of marked relief, often in lower valley sides or in valley bottoms (Figure 2). The first detailed description of open-system pingos was by Müller in East Greenland (Müller, 1959), but long-term studies of open-system pingo growth and decay have not been undertaken. Much less is therefore known, from direct observations, about their origins and internal structure than for closed-system forms.

Many open-system pingos occur in areas with thin and/or discontinuous permafrost. They have been described in central Alaska (Holmes et al., 1968), the Yukon Territory, Canada, the Tibetan Plateau, and central Yakutia, Russia. However, they are also found in areas of continuous permafrost, and have been recorded in Greenland (Müller, 1959; Worsley and Gurney, 1996) and Svalbard (Liestøl, 1977). Open-system pingos develop within a range of superficial sediments, including fluvial and slope deposits, and some even develop in weathered bedrock (Holmes et al., 1968; Liestøl, 1977; Müller, 1959). Open-system pingos are often somewhat smaller than their closed-system counterparts and are reported as single, isolated features and in clusters or groups of mutually interfering landforms of different ages.

The most widely cited model of open-system pingo formation is that of Holmes et al. (1968), who observed that nearly all pingos of Central Alaska lie on gentle to moderate slopes near the slope base in minor valleys and in gently sloping valley-bottom locations. Their preferential development on south- and southeast-facing slopes was attributed to thinner permafrost on slopes with these aspects. Holmes et al. (1968) suggested that local groundwater flow was crucial in determining the location and likelihood of open-system pingo development (Figure 4). Pressurized groundwater at intermediate depths beneath the valley sides has a tendency to flow toward the ground surface within subpermafrost unfrozen sediments or through bedrock fractures. Groundwater flow is restricted, however, by the base of the overlying permafrost, which acts like an aquiclude, confining upward flow (Figure 4). But near the base of the slopes – where the artesian pressure of groundwater sourced from the more elevated parts of the topography is greatest, and where thicker permafrost below the valley floor blocks the lateral flow of subpermafrost groundwater – water is forced upwards toward the ground surface. This water will either freeze in the near-surface to form a pingo, or – if it is too warm or the permafrost is locally absent – it will issue from the ground surface as a spring. Whether one or the other develops appears to be a very delicate balance of local thermal and geological conditions: Holmes et al. (1968) reported active and apparently perennial springs in association with some open-system pingos, a feature also characteristic of open-system pingos in Greenland and Svalbard.

In Eastern Greenland, open-system pingos are formed in glaciogenic materials, alluvial sediments, and bedrock in the

continuous permafrost zone, where mean annual air temperature is around -10°C and permafrost is recorded to a depth of 220 m. Here, the hydraulic system leading to pingo growth is probably fed, to some degree, by deep intra- or subpermafrost groundwater (Müller, 1959; Worsley and Gurney, 1996), rather than by significant amounts of recharge from seasonal surface melt. The postulated deep origins for these waters is supported by measurements of warm ($>0^{\circ}\text{C}$) and highly mineralized water discharging from perennial groundwater springs close to pingos in northeast Greenland; in winter, the springs form large surface icings. These characteristics suggest geothermal warming of ground waters, perhaps as they percolate along structurally controlled seepage zones and through taliks determined by zones of high geothermal heat flow (Worsley and Gurney, 1996). Interestingly, some Greenland pingos occur in localized clusters. This tendency has been attributed not only to the importance of regional hydrogeology in determining localities suitable for pingo development, but also to the evolution of very localized groundwater pathways through time.

On Svalbard, open-system pingos are also common in valleys. A simple but elegant model that suggested a close link between the pingos and polythermal glaciers on Svalbard was proposed by Liestøl (1977). Although permafrost is thick ($\sim 100\text{--}200\text{ m}$) and continuous beneath the inland parts of Svalbard, Liestøl (1977) recognized that it thins rapidly beneath the margins of the polythermal glaciers, and is probably entirely absent beneath the thicker warm-based ice beneath glacier accumulation areas. Subglacial meltwaters are therefore able to recharge groundwater where permeable strata underlie the warm-based parts of these glaciers. This provides a major source of meltwater to maintain (and pressurize) the groundwater throughout a significant part of the year, despite the continuous nature of the surrounding permafrost. Beyond the glacier margins – in a system akin to that responsible for the development of Alaskan open-system pingos (Figure 4) – this glacier-sourced groundwater is able to migrate through confined subpermafrost aquifers, within which considerable artesian pressures can be generated. In large, broad valleys such as Reindalen (Figure 5), this artesian pressure is sufficient for groundwaters to reach the near-surface, where freezing can generate open-system pingo growth. As suggested for Greenland, groundwater flow paths in Svalbard may also be influenced by the geological structure and geothermal heat. Deep percolation and geothermal heating of groundwater are indicated by the warm surface springs in parts of western Svalbard (Liestøl, 1977). Many pingos in Svalbard also show surface discharge of water (Figure 2) whose elevated salt content significantly lowers the freezing point. Other similarities may exist between the open-system pingos of Greenland and Svalbard, inasmuch as deep groundwaters in Greenland are also likely to have their initial origins in glacial meltwaters, probably from the Greenland Ice Sheet.

A subtype of open-system pingo has been identified in low-lying areas below the maximum Holocene sea level in Svalbard and Greenland. These landforms presumably date from the late to mid-Holocene and formed where, following relative sea-level fall, permafrost has aggraded in newly exposed and highly frost-susceptible fine-grained marine muds that favor

Figure 4 Cycle of formation and decay of open-system pingos. (a) Percolation of subpermafrost groundwater within a confined aquifer and injection into thin permafrost, initiating formation of a pingo ice core. (b) Formation of cracks due to tensional stresses developed as the surface is stretched by updoming of pingo center. (c) Development of central crater with pond as the ice core decays. Modified from Holmes GW, Hopkins DM, and Foster HL (1968) Pingos in central Alaska. *United States Geological Survey Bulletin* 1241-H: H1–H40; Ballantyne CK and Harris C (1994) *The Periglacialization of Great Britain*. ice segregation and frost heave (Ross et al., 2007). As a consequence, these pingos may be intermediate between closed- and open-system types. Such near-shore pingos, however, also share many characteristics with lithalsas.

Pingo collapse

Pingo degradation is normally initiated by the development of radial dilation cracks and concentric cracks caused by tensional stresses arising from bending and extension of the frozen overburden during pingo growth (Figures 4 and 6; Mackay, 1988). Sediment covering the ice core is lost because of slumping and solifluction of the active layer on the steep pingo sides (Babinski, 1982; Mackay, 1988), leading to the exposure of the pingo ice core, which is then highly susceptible to melting in summer months.

Figure 6 Closed-system pingo in the Mackenzie Delta, Canada, showing development of radial dilation cracks caused by tensional stress generated by upward growth. The exposed ice core is susceptible to thawing, initiating pingo collapse. Photograph by Charles Harris.

Figure 8 A collapsed closed-system pingo, Mackenzie Delta area, Canada. The pingo has an external diameter of approximately 250 m. Photograph by Ross Mackay.

Figure 7 Frozen lake within the crater of an open-system pingo, Reindalen, Svalbard. Photograph by Neil Ross.

Once melting of the ice core begins, the landform can be susceptible to an important positive feedback. As the ice core melts, a summit crater is generally formed, surrounded by a complex arrangement of ridges and mounds. These ridges may impound meltwater from the melting ice core, to form a lake. Crater lakes, many with perennial groundwater springs and outflow streams, have been reported from active pingos in Canada (Mackay, 1988), Greenland (Müller, 1959), Svalbard (Liestøl, 1977), Mongolia (Babinski, 1982), and Alaska (Holmes et al., 1968) (Figure 7). Because of the high thermal conductivity of water, melting of the underlying ice core can occur rapidly beneath these water bodies. The lake will also generally increase the rate at which lateral (thermal) erosion of the surrounding frozen ridge occurs. As degradation progresses, the lake increases in diameter, further increasing (i) the surface area of the ice core subject to melt and (ii) the length of crater-lake shoreline subject to thermal erosion.

Some processes, however, slow the rate of degradation. Intermittent, sometimes seasonal, breaching of crater lakes will result in outflow from, and possibly drainage of, the enclosed basin. If a crater-lake drains completely, then the rate of landform degradation may reduce significantly. Inward movement of thawing sediment from the crater rim is also

possible once degradation is well advanced, and this may also slow the degradation of the ice core by insulating it from warm air temperatures.

Complete landform degradation often leaves a pond surrounded by a circular, sometimes ice-cored, ridge of sediment. Although mature collapsed pingos with ramparts have been described from the contemporary permafrost zone (Figure 8; Babinski, 1982; Holmes et al., 1968; Mackay, 1988; Müller, 1959; Worsley and Gurney, 1996), there have been few investigations of their internal structures. Solifluction and slumping are clearly important processes in their development, as they result in a net transfer of sediment to the base of the mound where it accumulates to form a circular ridge. In addition to mass-movement processes, however, short-lived streamflow events may also play an important role in the redistribution of sediment necessary to form rampart ridges around collapsing pingos. Small-scale outlet channel forms, associated with small alluvial fans, have been observed around the periphery of several collapsing pingos (Mackay, 1988; Müller, 1959).

Other Frost Mounds

In addition to closed- and open-system pingos, arrays of smaller seasonal and perennial ground-ice mounds have been recognized. This section describes seasonal frost mounds, palsas, mineral palsas, and lithalsas. Because seasonal frost mounds and palsas have limited long-term preservation potential, emphasis is given here to mineral palsas and lithalsas, which are more likely to be represented in the Quaternary record.

Seasonal frost mounds

Ephemeral frost and icing mounds or blisters (Pollard, 1988), usually less than 5 m high, form in permafrost regions as a result of winter freeze-back of the active layer, trapping supra-permafrost groundwater fed by springs. Mounds are mantled with a thin layer of peat and soil, underlain by mineral soils, and contain bubble-rich or clear ice cores. These are sometimes layered and sometimes arched over a water-filled chamber within which sufficiently high hydrostatic pressures are developed in winter to uplift and deform the frozen overburden. Such landforms have a low preservation potential in the

Figure 9 Palsa mire, northern Finland, with low palsa mounds in the background and a decayed and collapsed mound in the foreground. Photograph by Matti Seppälä.

geological record and are unlikely to be found, or easily identified, in areas formerly affected by permafrost.

Palsas

Palsas are low permafrost mounds, up to around 7 m high and commonly up to 30 m in diameter (Figure 9). [Pissart \(2002\)](#) described palsas as “perennial mounds covered in peat, situated in the discontinuous permafrost zone and due chiefly to segregation ice fed by cryosuction.” Palsas develop in peatland mires in the circumpolar discontinuous or sporadic permafrost zones, and are normally observed in groups or ‘fields’ ([Gurney, 2001](#)). They form as a result of differential winter frost penetration. Deeper frost penetration in areas with thinner snow cover leads to frost heave due to ice segregation. The more deeply frozen peat is frost-heaved above the surrounding landscape, and in summer its surface layers dry, forming an effective insulating cover that limits the depth of thaw and preserves a frozen core beneath the palsa. During succeeding winters, snow is blown from the upper surface of the growing palsa but accumulates in the low-lying wetter areas, causing further differential frost penetration, ice segregation, and palsa growth ([Gurney, 2001](#)).

Palsas eventually decay when erosion of their sides and loss of peat cover from their top cause the frozen core to melt and collapse ([Gurney, 2001](#)). This often forms ponds (Figure 9) that are occasionally surrounded by a low ridge. Such ponds, however, rapidly fill with peat and their preservation potential is extremely low. All stages of cyclic palsa evolution (growth, maturity, and collapse) can commonly be observed in the same mire, though there is recent evidence for climatically driven degradation of palsa mires in Scandinavia and North America.

Mineral palsas and lithalsas

The frozen core of a palsa may extend through the peat cover into underlying frost-susceptible sediments. These sediments are heaved upwards by the formation of segregation ice, fed by cryosuction, to form a domed mineral core ([Gurney, 2001](#); [Pissart, 2002](#)). The peat cover of such ‘mineral palsas’ may be <10 cm thick and they appear to form part of a continuum of landforms caused by local redistribution of winter snow, differential frost penetration, and associated differential heave. At one end member are palsas formed entirely in peat, and at the

Figure 10 Decaying mineral palsas or lithalsas with central ponds and raised rims, 20 km inland from the eastern coast of Hudson Bay, near Umiujaq, northern Quebec, Canada. The features are developed in marine silts. Photograph by Michel Allard.

other are low (<10 m high) perennial frost mounds developed in sediments with little or no peat cover ([Gurney, 2001](#); [Pissart, 2002](#)). To distinguish them from other types of palsa, circular to oval mounds formed in sediments with no peat cover have been named ‘lithalsas’ ([Pissart et al., 1998](#)).

Mineral palsas and lithalsas occur in extensive contiguous fields, with younger features commonly disturbing older ramparts and depressions (Figure 10). They are particularly common in Scandinavia and North America. Although normally developed in fine-grained lacustrine and marine sediments ([Allard et al., 1987](#); [Pissart et al., 1998](#)), they can also form in areas with marine sands, in gravel, till, and stony glaciomarine diamicton ([Allard et al., 1987](#)). Besides being associated with low-lying zones of latitudinal permafrost, lithalsas have also been recognized in high-mountain environments. [Wünnemann et al. \(2008\)](#) mapped lithalsas at elevations >4500 m in the Himalayas. Unlike palsas developed entirely in peat, mineral palsas and lithalsas are more likely to generate enclosed rim-ridges during their collapse ([Gurney, 2001](#); [Pissart, 2002](#)). Because they are composed of mineral sediments, these landforms, like collapsed pingos, have much greater preservation potential than palsas.

Mineral palsa and lithalsa collapse

The growth of radial and concentric cracks, small-scale landsliding, thaw consolidation, and solifluction have all been reported from mineral palsas and lithalsas ([Allard et al., 1987](#); [Calmels et al., 2008a,b](#)). Like the collapse of pingos, the collapse of these smaller landforms results in the development of thermokarst depressions surrounded by ring-ridge ramparts (Figure 10). These are composed of mineral sediments accumulated by mass movement, as well as through lateral compression due to the growth of segregation ice ([Calmels and Allard, 2008](#)).

There is some evidence for a general trend of mineral palsa and lithalsa degradation in response to twentieth-century warming, although some studies emphasize the influence of local hydrology on their growth or decay. For example, [Lewkowicz and Coultish \(2004\)](#) showed that mineral palsa formation was controlled by the influence of beaver on the

local environment: frost-mound degradation followed flooding due to dam construction, and growth occurred after dams were breached and the ground surface was exposed. This unusual example clearly shows the influence that local hydrology has on frost-mound development, particularly in the sporadic or discontinuous permafrost zones.

Active frost mounds: a summary

Frost-mound growth depends on a complex interplay of processes and environmental conditions. Growth is strongly controlled not just by the presence or absence of permafrost (and hence the climatic regime), but also by the regional and local hydrogeological conditions, glacier meltwaters, geological structure, and the geothermal heat flux. Such complexity must be considered when interpreting Quaternary landforms that have all the hallmarks of relict frost mounds.

Relict Frost Mounds

Enclosed depressions surrounded by annular ring-ridges or ramparts have been interpreted as remnant landforms that mark the former location of Quaternary frost mounds. They are frequently found in clusters, and, in Western Europe, are sited on valley bottoms, at slope–valley interfaces, and in some plateau locations. Various terms have been introduced to describe these relict features. Given the complexities of interpretation, however, terms such as ‘relict frost mound’ or ‘ramparted depression’ are preferred to those with genetic connotations such as ‘pingo scar.’ Useful reviews of ramparted ground-ice depression sites of Pleistocene age from northwest Europe and North America are given by [Flemal \(1976\)](#) and [Pissart \(2003\)](#).

In Quaternary ramparted depressions, the ramparts may contain overturned, deformed, and tilted stratified sediments overlain by mass-movement deposits showing crude radially dipping stratification ([Pissart, 2000](#); [Ross et al., 2011](#)). The presence of these structures often provides important evidence for an origin related to the decay of ground-ice mounds.

The classic site where Pleistocene ramparted depressions were first detailed is on the Hautes Fagnes Plateau, Belgium. Here, enclosed, peat-filled depressions surrounded by distinct ramparts are widespread. The ramparts are commonly less than 1 m high, but some reach a height of 5 m ([Pissart, 2000, 2003](#)), and the thickness of basin infill varies between 1 and 7.5 m, with diameters of up to several hundred meters. These features were first interpreted as the remains of open-system pingos of the Younger Dryas age, dated by radiocarbon, tephra, and pollen stratigraphy methods ([Pissart, 2000, 2003](#)). The absence of an obvious aquifer to supply groundwater subsequently led Pissart to conclude that segregation ice rather than injection ice was responsible for the development of these landforms, and that they represent former lithalsas rather than open-system pingos. Their ramparts are thought to have formed by lateral compression and accumulation of slumped sediment ([Pissart, 2000](#)).

In Scandinavia and the British Isles, relict ramparted depressions ([Figure 11](#)) formerly interpreted as open-system pingos have also been reinterpreted as lithalsa remnants ([Pissart, 2000, 2003](#)). [Pissart \(2002\)](#) argued that the known spatial characteristics of contemporary pingos (widely spaced,

Figure 11 Relict ramparted depression thought to mark the former location of a Quaternary frost mound, Llanpumsaint, Wales, UK. Photograph by Neil Ross.

low number per unit area) and lithalsas (groups of closely spaced landforms, often very numerous, with a high concentration per unit area) allow simple interpretation of relict Pleistocene landforms. Interpretation of ramparted depressions becomes more complicated, however, when it is accepted that in past and present glaciated regions burial and subsequent melting of marginal glacier ice can form landforms topographically similar to those produced by the collapse of frost mounds. Extensive areas with ramparted depressions in the northern North American Prairies have long been interpreted not as ground-ice-related phenomena but as the product of subglacial and supraglacial processes ([Flemal, 1976](#); [Iannicelli, 2003](#); [Mollard, 2000](#)). Similar interpretations have been proposed in Scandinavia. Icebergs, grounded by lake drainage, have also been used to explain ring-ridges ([Mollard, 2000](#)). Therefore, while many European researchers have favored a periglacial origin for ramparted depressions, the North American literature tends to favor a glacial origin ([Flemal, 1976](#)). Contemporary studies in permafrost regions aimed at assessing the processes of pingo decay and collapse are therefore critical for the accurate identification and classification of relict Pleistocene ramparted ground-ice depressions. Recent studies of ramparted depression in Europe have been more aware of the risks associated with assuming that ramparted depressions represent a relict permafrost landform and have also assessed potential glacial origins ([Ross et al., 2011](#)). Even when detailed sedimentological and geophysical data are available from particular sites, however, precise interpretation is frequently difficult, given (i) the range of frost-mound types identified in modern cold environments and (ii) the array of glacial processes that can lead to the burial and melt-out of glacier ice, and therefore the formation of topographic depressions with enclosing ridges or ramparts.

Recent Developments in Frost-Mound Research

Several key factors have limited our understanding of frost-mound-related processes. These are (i) a lack of natural exposure (of both the internal structures of frost mounds and the surrounding host material), (ii) the cost and logistical challenges associated with creating artificial exposures (e.g., by drilling) in remote high-latitude permafrost environments, (iii) too great a focus on site-specific studies, and (iv) a lack of long-term monitoring. This section outlines a series of recent studies that have begun to address these research shortcomings.

To overcome the lack of natural exposure of frost-mound internal structure, and the costs associated with drilling, several recent studies have applied geophysical tools (ground penetrating radar, electrical resistivity, seismic, and electromagnetic

techniques) to image the internal structures of frost mounds (Fortier et al., 2008; Ross et al., 2007; Yoshikawa et al., 2006). Because of the contrasting physical properties of unfrozen water, ice, and host geological materials, these techniques offer significant potential for characterizing the internal structures, ice content, and host materials of frost mounds, which can then be used to infer the likely mechanisms of formation. The most comprehensive of these studies is that of Yoshikawa et al. (2006), who integrated a suite of ground and airborne geophysical data with borehole data to constrain the internal structures of open-system pingos in Alaska. These authors showed that two-dimensional (2D) electrical resistivity tomography seems to be the most successful single technique for imaging pingo internal structures (although it is best combined with others). Because pure ice is highly resistive, electrical resistivity is normally extremely useful for delineating the massive ice core in pingos; values of $>10\,000\ \Omega\ \text{m}$ are common for pingo cores (Yoshikawa et al., 2006). Ross et al. (2007) have shown, however, that the response of the pingo core can be highly dependent on the host material and the type of ice (injection or segregation ice). Near-shore open-system pingos in Svalbard are characterized by very low values of resistivity ($<2000\ \Omega\ \text{m}$) for permanently frozen ground. These results were attributed to pingo growth by segregation-ice development within fine-grained, saline marine clays (Ross et al., 2007), a mechanism not dissimilar to that by which lithalsas form.

Research into present-day frost mounds has tended to be rather focused on site-specific investigations and has, arguably, ignored the 'bigger picture.' Small-scale Geographic Information System (GIS) and remote-sensing studies of high-latitude environments show considerable potential for addressing this shortcoming and for contributing toward our understanding of frost-mound development. By far, the best example of this is the study of Grosse and Jones (2011), who compiled a geodatabase of over ~6000 pingos from openly accessible Russian map and remote-sensing datasets, and used GIS tools to analyze the spatial distribution of these landforms across Northern Asia. By integrating open-access permafrost, geological, climatological, hydrological, and elevation datasets, they were able to (i) quantify the key factors for pingo development across northern Asia (near-surface geology and hydrology), (ii) delimit the range of mean annual ground and air temperatures that the pingos in the region of study were found in, (iii) propose that 34% of the pingos studied are located in areas where climate models predict permafrost thaw by 2100, and which may initiate pingo degradation, and (iv) provide an up-to-date figure for the number of pingos on Earth ($>11\,000$).

Thanks to the work of Mackay (1998), closed-system pingos have been the subject of long-term monitoring studies, revealing key data concerning both internal structures and the way in which this type of frost mound forms and degrades. Until recently, however, comparable monitoring studies had not been undertaken on other types of frost mound. In 2000, a long-term monitoring and investigative study of a lithalsa was initiated in Quebec (Calmels et al., 2008a,b and references therein). During the period of monitoring (2000–2005), the lithalsa showed a pattern of long-term degradation, including the initial stages of rim-ridge formation (Calmels et al., 2008a). Tomodensitometric scanning of cores from the monitored lithalsa revealed unparalleled information regarding the ice

and gas content within the landform, while ground temperature measurements were used to infer the processes of groundwater migration and ice-lens growth (Calmels et al., 2008b). Long-term monitoring studies such as this provide critical information, and if we are ever to fully understand the mechanisms that drive the evolution of other frost mounds (e.g., open-system pingos), it will only be achieved through systematic investigations similar to those undertaken by Calmels et al. (2008a,b) on lithalsas.

The quantitative studies outlined above demonstrate that frost-mound research has clearly explored new and exciting avenues in recent years, not just by embracing and applying modern and novel techniques (geophysics and GIS) but also by doing the 'basics' correctly (through the setting up of long-term monitoring programs). These studies have provided important information regarding the processes responsible for the growth and collapse of modern-day frost mounds, information that is critical for making accurate interpretations of the likely mechanisms responsible for the formation of Quaternary ramparted depressions.

Slope Deposits and Forms

C Harris, Cardiff University, Cardiff, UK

© 2013 Elsevier B.V. All rights reserved.

Periglacial slope processes are largely controlled by ground freezing and thawing leading to rock weathering, frost heave, and thaw consolidation. Rock weathering is predominantly mechanical and releases rockfalls on steep slopes that form scree deposits. Frozen sediments within permafrost and within the seasonally frozen active layer are frequently ice rich and therefore produce high moisture contents when they thaw. Periglacial regions are therefore very susceptible to both rapid slope failures and accelerated soil creep or solifluction, and mass movement deposits frequently mantle both modern and relict periglacial slopes.

Where scree materials lying within the permafrost zone contain interstitial ice—for instance, through burial of snow by rockfall—creep deformation of the frozen ground may generate distinctive flow structures, termed rock glaciers. The presence of a shallow active layer over a largely impermeable permafrost table promotes overland flow and slope wash. In steeper terrain, debris flows are common where either rapid snowmelt or high-intensity rainfall events release large volumes of water into the active layer. Thus, the range of slope processes and landforms in periglacial regions is high although in general dominated by gravitational mass movement. Periglacial processes frequently operate on pre-existing glacial terrain and contribute to the rapid ‘paraglacial’ landform adjustment that follows deglaciation.

Significance of Ground Freezing and Thawing

Permafrost regions are characterized by seasonal thawing and refreezing of the active layer, whereas in non-permafrost periglacial regions, winter frost penetrates into the ground from the surface. Where winter temperatures are variable, such as many mid-latitude mountain regions, freezing may be interrupted by periods of thaw. In high mountains at low latitudes, diurnal freezing and thawing cycles frequently dominate.

Water occupying pore spaces in sediments (and in porous rocks) does not all freeze at 0 °C. Thin films that wet the soil particles form a layer of bound water that freezes at temperatures well below zero (Williams and Smith, 1989; Yershov, 1998). Much of the pore water in fine-grained sediments may therefore remain unfrozen at subzero temperatures. Ice crystallization begins within slightly larger pore spaces that contain free or only weakly bound water, and here phase change leads to formation of lenticular ‘segregation ice.’ Progressive phase change sets up a cryosuction below the freezing front, causing water to migrate toward it from unfrozen zones below, to supply continued ice lens growth. This ice segregation process leads to an increase in volume of the frozen soil and frost heave of the surface, with ice contents in the frozen ground well in excess of the natural saturated moisture content. Silts and clays are prone to ice segregation when they freeze and are termed ‘frost-susceptible’ soils.

In seasonally frozen ground where no permafrost is present, and in the active layer above warm permafrost, segregation ice is likely to be evenly distributed provided there is a supply of water. However, where water is limited, ice segregation is concentrated in the upper part of the frozen profile. Within the active layer above cold permafrost, water can migrate downwards in summer to supply the growth of ice lenses in the base of the active layer and top of the permafrost. Thus, the phenomenon of ‘summer frost heave’ may be observed, associated with the development of an ice-rich zone at the permafrost–active layer interface (Mackay, 1983). In winter, a freezing front penetrates upwards from the permafrost table as well as downwards from the ground surface, leading to water migration toward both freezing fronts, leaving the central active layer relatively dry and ice-free.

Thawing of ice-rich frozen sediments is accompanied by closure of voids previously occupied by ice lenses and expulsion of the excess water they contain. This thaw consolidation process causes a reduction in soil volume and settlement at the surface. However, low permeability of the overlying thawed soil limits the rate at which excess water can be expelled (the still-frozen substrate below is largely impermeable). During this period of thaw settlement, self-weight stresses are transferred from particle contacts to the soil water, raising pore water pressures and reducing effective stress. The soil becomes soft and easily deformed, promoting downslope gravitational mass movement by solifluction and, in extreme cases, landslides.

The generation of pore water pressures during soil thaw depends largely on the ratio between the rate of thaw (which governs the rate of meltwater release) and the rate of consolidation (which is controlled by the rate of expulsion of excess meltwater). This ratio, the thaw-consolidation ratio, forms the basis of the thaw-consolidation theory (McRoberts and Morgenstern, 1974). Thus, a high value of R (approaching or greater than 1) indicates rapid thaw and slow drainage, a condition likely to raise pore pressures and reduce effective stresses, whereas a low value of R indicates slow thaw penetration, rapid drainage, and little tendency for excess pore pressures to develop.

Slow Mass Movement

Solifluction

The term solifluction was defined originally by Andersson (1909) as “slow flowing from higher to lower ground of masses of waste saturated with water” but was not restricted to cold climates. Washburn (1979) suggested the term gelifluction be used for saturated soil movement specifically associated with ground thawing. Since both frost creep and gelifluction are caused by frost heaving and subsequent thaw settlement, in practice they are often impossible to differentiate

in field measurements (Harris, 1981) and the term solifluction is now commonly used to include all such processes contributing to slow periglacial mass wasting in which surface displacement rates range from several millimeters to several tens of millimeters per year (Ballantyne and Harris, 1994). The process is commonly the dominant mechanism of sediment transport on periglacial slopes (Matsuoka, 2001).

Frost Creep

Frost creep, one of the main components of solifluction, is defined as the slow downslope gravitational deformation of slope materials caused by diurnal and annual cycles of freezing and thawing that lead to frost heave perpendicular to the slope surface followed by more nearly vertical thaw settlement (Washburn, 1979). Surface tension between soil grains creates apparent cohesion that prevents truly vertical resettlement, but during each freeze–thaw cycle there is a net downslope displacement of the disturbed soil. Maximum potential frost creep is given by vertical settlement and equals the product of frost heave and the tangent of the slope angle. Thus, the annual rate of surface movement depends on the amount of heave, the slope angle, and the frequency of frost heave cycles. Since diurnal freezing cycles generally penetrate only a few centimeters into the ground, associated frost creep affects only the uppermost few centimeters of soil (Matsuoka, 1998). Surface frost creep rates generally increase toward the surface, are generally less than 1 or 2 cm per year, and the depth of displacement depends largely on the depth of frost penetration but is usually less than 30 cm (Matsuoka, 2001).

Certain periglacial slopes may be affected by the diurnal formation of needle-like ice crystals a few centimeters in length that grow in clusters upward from the soil surface. Needle ice requires a frost-susceptible soil, a good supply of water from below, and sufficient permeability to allow rapid moisture migration to the freezing front. The rate of release of latent heat during phase change prevents downward advance of the freezing front and allows ice crystals to grow upward, perpendicular to the ground surface. Diurnal needle ice growth can lift soil particles and stones 50 mm or more. Higashi and Corte (1971) showed that surface displacements may exceed the potential frost creep value as a result of particle rolling and deformation of the supporting ice needles prior to thaw so that where needle ice cycles are frequent, rates of surface displacement may total several hundred millimeters per year.

Gelifluction

Gelifluction is the slow gravitational shear deformation of fine-grained frost-susceptible sediments (although such sediments may also contain abundant larger clasts) associated with high moisture contents and high pore pressures generated during thaw consolidation of ice-rich frozen ground. In a series of laboratory experiments simulating gelifluction in a silty ice-rich soil, Harris et al. (1997, 2001, 2003) demonstrated that pore pressures rise rapidly immediately following thaw (Figure 1), at which time the newly thawed soil has a low density, high moisture content, and an extremely low shear strength, making it susceptible to deformation under gravitational stresses below the threshold for slope failure.

Figure 1 Pore pressures recorded during experimental simulation of solifluction. Data relate to the second thaw cycle in a 1/10-scale planar slope model of gradient 12° constructed of frost-susceptible natural fine sandy silt collected from Vire in Normandy, France. The model was thawed under a gravitational acceleration of 10 gravities in the geotechnical centrifuge (Harris et al., 2001). Time and depth are scaled to the equivalent prototype scale. Arrows indicate time of thawing at the respective transducer depths.

Field measurements in Greenland by Washburn (1967) demonstrated surface movement through an annual cycle of surface-downward freezing and thawing (Figure 2a). Winter frost penetration from the surface caused frost heave (displacement from P1 to P2 in Figure 2a), and in spring, thaw of the ice-rich active layer from the surface resulted initially in combined surface settlement and downslope displacement (P2 to P3 in Figure 2a) and, finally, in thaw settlement approximately perpendicular to the soil surface, reflecting the closure of the voids but no further downslope movement (P3 to P4 in Figure 2a). Full-scale laboratory simulation of gelifluction by Harris and Davies (2000) demonstrated very similar soil surface movements through a cycle of downward freezing and downward thawing (Figure 2b). In cold permafrost regions, however, little active-layer displacement may occur until late in the summer, when the ice-rich basal zone begins to melt. At this time, the active layer moves downslope en masse across the deforming basal zone softened by high pore pressures generated during thaw consolidation (Lewkowicz and Clarke, 1998). Such late summer gelifluction was termed ‘plug-like flow’ by Mackay (1981) and has been modelled in large-scale laboratory experiments that simulated a sloping active layer above ice-rich permafrost (Harris et al., 2008).

Several authors have described gelifluction as the slow viscous flow of soil that occurs annually during thawing when field moisture content exceeds the liquid limit (Smith, 1988; Harris et al., 1997). However, scaled simulation modeling in a geotechnical centrifuge by Harris et al. (2003) demonstrated that soil deformation during gelifluction is not a viscosity-controlled process but, rather, the prefailure elastoplastic deformation of a frictional soil whose strength is controlled largely by pore water pressures. Profiles of soil movement have been observed through burial and reexcavation of marker columns and tubes. Matsuoka (2001) identified four styles of slow periglacial mass movement associated with (a) frost creep due to diurnal needle ice, (b) frost creep due to diurnal segregation ice, (c) frost creep and gelifluction due to one-sided

Figure 2 (a) Measured surface displacements, Mesters Vig, Greenland, over an annual cycle of ground freezing and thawing (Washburn, 1967). PFC, horizontal component of potential frost creep (with vertical resettlement of soil); G, horizontal component of gelifluction (downslope displacement in excess of potential frost creep); R, horizontal component of retrograde movement due to resettlement perpendicular to the soil surface. (b) Observed surface displacement over a cycle of ground freezing and thawing in an experimental simulation of solifluction processes. seasonal ground freezing, and (d) plug-like flow due to two-sided active-layer freezing (Figure 3).

Sediment Transport Rates

Measured solifluction transport rates in present-day non-permafrost periglacial regions are generally between 20 and $50 \text{ cm}^3 \text{ cm}^{-1} \text{ yr}^{-1}$, with a maximum close to $120 \text{ cm}^3 \text{ cm}^{-1} \text{ yr}^{-1}$ (Matsuoka, 2001). In permafrost regions, transport rates are slightly higher, ranging up to $230 \text{ cm}^3 \text{ cm}^{-1} \text{ yr}^{-1}$, mainly due to the greater thickness of active layer affected by plug-like solifluction. Thus, sediment transport rates due to solifluction are one or more orders of magnitude higher than transport rates due to soil creep in humid temperate regions. State-of-the-art field instrumentation for monitoring of solifluction is described by Harris et al. (2007) and Matsuoka (2010).

Many hill slopes in the nonglaciated temperate zone, such as southern Britain, show clear evidence of Quaternary periglacial solifluction processes, both in their slope profiles and in their mantle of relict periglacial slope deposits dating to late Pleistocene cold stages (Ballantyne and Harris, 1994).

Landforms

On mountain slopes, solifluction rates vary in response to changing soil properties, vegetation, drainage, snow cover, and topography. Sediment accumulation in zones of slower movement leads to formation of distinctive step-like landforms referred to as solifluction lobes or terraces (Harris, 1981). Frost sorting and differential movements often result in a concentration of clasts in the risers, producing 'stone-banked' lobes and terraces, in contrast to those with vegetation-covered risers termed 'turf-banked' (Benedict, 1970). Solifluction lobes have risers up to approximately 1.5 m high, whereas tread lengths are a function of the frequency of lobes on a given profile but generally range up to several tens of meters (Figure 4a). Solifluction terraces are larger, with risers up to 3 m high, although risers up to 6.5 m high have been reported (Harris, 1981). Detailed morphological analyses of solifluction lobes have been carried out by Hugenholtz and Lewkowicz (2002) and Matsuoka et al. (2005). In continuous permafrost regions, solifluction rates are more uniform, and lobes and terraces are generally not observed. Here, solifluction tends to produce smooth convexo-concave

Figure 3 Typical frost creep and gelifluction displacement profiles: (a) diurnal needle ice, (b) diurnal frost penetration and formation of segregation ice, (c) seasonal frost penetration and formation of segregation ice, and (d) two-sided active-layer freezing above cold permafrost. Note the depths of soil displacement vary with depth of frost penetration or, in the case of permafrost, depth of summer thaw. Surface movements shown represent accumulated movement over several years. Classification based on Matsuo (2001).

slopes, sometimes with streamlines marked by elongation of surface patterned ground (Figure 4b).

During solifluction, coarser clasts are carried downslope within a deforming fine soil matrix, and as a result, distinctive shear fabrics develop in which elongates show a strong preferred downslope orientation, often with a slightly imbricate dip relative to the ground surface (Harris, 1981). At lobe and terrace fronts, transverse clast orientations approximately parallel to the alignment of the riser are observed, with b-axes dipping upslope. In many turf-banked solifluction lobes, downslope movement over the ground surface below leads to burial of soil and vegetation beneath the advancing lobe front. Excavation often reveals a complex series of buried soils extending beneath the lobe upslope from the front, and radiocarbon dating has allowed reconstruction of past rates of lobe frontal advance and, therefore, past variations in intensity of solifluction (Benedict, 1970; Matthews et al., 2005).

Rapid Mass Movements

Active-Layer Detachment Slides

These are shallow landslides developed in thawing soil overlying permafrost (Figure 5a). They occur on gentle to moderate slopes and are reported from North America and parts of

Siberia (Lewkowicz and Harris, 2005). Related ribbon-like flow-dominated slope failures common in the discontinuous permafrost zone following forest fires were referred to as 'skin-flows' by McRoberts and Morgenstern (1974). Observational evidence suggests that active-layer detachment slides may form rapidly, within a day, but may continue to be sporadically active over several days or even years (Lewkowicz, 1992, 2007). Slides are translational in nature, with the displaced mass maintaining its coherence over a basal shear zone and displaying lateral and terminal compression ridges containing multiple thrust blocks (Harris and Lewkowicz, 1993).

Detailed investigations of detachment slides in Canada, in the continuous permafrost zone of Ellesmere Island and the discontinuous permafrost zone of the Mackenzie Valley, have shown median length-to-width ratios of between 2.4 and 3.6 (Lewkowicz and Harris, 2005) and median depth-to-length ratios of 1 to 2%. Such extremely shallow landslides would be associated with flow-type failure in non-permafrost regions, but the presence of an ice-rich zone immediately above the permafrost table coupled with rapid thaw rates initiated by high late summer temperatures in Ellesmere Island and forest fire in the Mackenzie Valley (Harris and Lewkowicz, 2000) result in sufficiently high basal pore pressures to initiate slope failure even under the extremely low stress conditions on slopes as gentle as 5–10°. Coherence of the displaced active

Figure 4 (a) Solifluction lobes in Jotunheimen, southern Norway, an area of seasonal frost penetration without permafrost. Lobe fronts are up to 1.5 m high. (b) Solifluction sheet, Ellesmere Island, Canada. This is an area of continuous permafrost, with active-layer depths less than 1 m, where with two-sided active-layer freezing causes plug-like flow (see Lewkowicz and Clark, 1998).

layer in Ellesmere Island detachment slides is due to two-sided freezing that generates cryosuction, causing water migration toward both the surface and the base of the active layer, leaving the central zone overconsolidated, dry, and stiff.

Ground-Ice Slumps

These are deeper slope failures that develop when ice-rich permafrost (as opposed to the active layer) becomes exposed to rapid thaw degradation, usually as a result of lateral erosion by rivers, lakes or coasts. The exposed ice-rich permafrost thaws back to form an embayment, releasing mudflows that carry away soft and very wet mud (**Figure 5b**). The rate of retreat of the ice-rich headwall depends on the air temperature, exposure to solar radiation, ground ice content, and sediment cover and features may persist for several years. Such slump structures developed in ice-rich permafrost are a component of thermokarst.

Debris Flows

Debris flows are common in mountain regions where gradients are steep. Although not restricted to the periglacial zone (**Coussot and Meunier, 1996**), debris-flow initiation is facilitated by the presence of thin debris covers on steep slopes that

Figure 5 (a) Active-layer detachment slides, Ellesmere Island, Canada. The slide depth is generally less than 1 m and the length of the largest slide shown is approximately 750 m. (b) Ground-ice slump caused by lateral erosion by river exposing near-surface ground ice. Note rectangular-shaped ice-wedge polygons in the background.

are underlain by an impermeable permafrost table or shallow bedrock. Heavy rainfall events lead to rapid saturation of the debris, the development of seepage pressures, and initiation of rapid flows with high water contents (**Larsson, 1982**). The flow track is ribbon-like, flanked by bouldery levees, and terminates in a lobate fan-shaped frontal zone.

Relict Periglacial Slope Deposits

Where Quaternary cold stages were associated only with periglacial environments rather than glaciation, such as in southern England and northern France, slope deposits are locally derived (although sometimes with the addition of windblown loessic silts) and therefore closely reflect the lithology of the underlying bedrock. **Harris (1987)** and **Hutchinson (1991)** identified two distinct classes of periglacial slope deposits on the basis of their parent materials: coarser granular deposits derived from non-argillaceous bedrocks and clay-rich deposits derived from argillaceous bedrocks. Where Quaternary glaciation has occurred, tills are frequently reworked by subaerial cold-climate slope processes immediately following deglaciation, and they may closely resemble granular periglacial slope deposits. The presence of erratic clasts with surface striations and edge rounding, and a higher proportion of fines, may be used to identify such paraglacial deposits (**Harris, 1998**).

Granular Periglacial Slope Deposits

In Britain, granular periglacial slope deposits are often mapped as 'head deposits.' These generally comprise angular frost-weathered clasts derived from the underlying bedrock, set in a frost-susceptible silty to fine sandy matrix (Figure 6), and occur beneath smooth convexo-concave hill slopes, often thickening in the foot-slope zone to form several meters of valley fill. In coastal locations in both southern England and northern France, solifluction deposits mantle relict cliffs and bury raised beaches (Ballantyne and Harris, 1994). It is generally assumed that these deposits accumulated by solifluction, although rapid slope failures such as mudflows and detachment slides may

Figure 6 Head deposits, Wembury, south Devon. Bedrock is Devonian slate and the rockhead is progressively weathered and overturned as it merges upwards into the base of the head deposits.

also have been active, especially where slopes were steeper. Clasts show low-angle dips approximately parallel to the slope surface and are strongly oriented downslope.

Occasional layers and lenses of well-sorted silts and sands are thought to reflect episodes of slope wash and reworking of eolian silts. A common characteristic is a merging rockhead boundary in which bedrock becomes increasingly shattered, gradually merging upward into the base of the slope deposit and becoming overturned in a downslope direction (Figure 6).

In the chalklands of southern England, frost weathering driven primarily by seasonal freeze-thaw cycles has reduced near-surface chalk to a fine calcareous mud, which was apparently highly susceptible to solifluction. The resulting chalk head is termed 'coombe rock.' It forms a thin mantle over valley sides but thickens rapidly into the valley bottoms (Ballantyne and Harris, 1994). Coombe rock consists of silt-sized chalk powder containing occasional chalk clasts that become larger and more frequent closer to the rockhead and show strong downslope preferred orientations.

Periglacial Slope Deposits Derived from Clay Bedrock

Where bedrocks consist of clays and mudstones (e.g., the Lias clays of the Cotswolds and the Paleogene clays of southeast England), slope deposits comprise several meters of partially remolded clay, often containing fragments of more resistant sedimentary rocks derived from further upslope. Underlying and within these deposits are low-angle shear planes often lying approximately parallel to the ground surface (Chandler, 1972; Hutchinson, 1991; Ballantyne and Harris, 1994). Hutchinson (1991) and Spink (1991) illustrated the range of shears commonly observed in clayey periglacial solifluction deposits (Figure 7). The most extensive are the basal shears

Figure 7 Schematic diagram showing classification of periglacial shears based on Hutchinson (1991) and Spink (1991). Type 1 are discontinuous, subhorizontal solifluction shears (Spink, 1991) and include emergent shears (Hutchinson 1991). Type 2 are extensive basal shears approximately parallel to the ground surface. These occur at the base of the clay head and may also be found close to the surface of, but within, the disturbed clay below. Type 3 are small-scale discontinuous shears, termed accommodation shears by Spink, within the clay head material. Hutchinson describes the clay head as having a mudslide fabric. Type 4 are high-angle thaw collapse shears associated with thermokarstic ground subsidence. Type 5 are subhorizontal principal underthaw or deep-seated landslide shears. Type 6 are undulose discontinuous secondary underthaw shears. Spink also includes as type 7 subvertical cracks thought to be associated with contraction of the clay during drying, but these are not shear surfaces and they probably postdate the periglacial phase.

Figure 8 Model of ground disturbance associated with periglacial cambering based on the interpretation of Hutchinson (1991). The figure shows a hypothetical profile of lateral displacement. The clay head deposits are likely to be underlain by, and to contain, periglacial shear surfaces. Extrusion of clay above the basal décollement is considered to have resulted from upward thawing of the ice-rich permafrost base, resulting in softening by thaw consolidation.

over which the slope deposits have slipped. Smaller scale discontinuous shears within the displaced soil mass reflect internal deformation during mass movement.

These relict periglacial shear surfaces underlying clayey slope deposits indicate shallow translational landsliding, equivalent to the active-layer detachment slides of the present-day Arctic. Hutchinson (1991) illustrated the probable mechanism of failure (Figure 8). Since shear surfaces are observed beneath slopes as gentle as 4° , and very high pore pressures would be necessary to reduce the shear strength sufficiently to induce failure, it is concluded that the only mechanism capable of generating such high pore pressures is thaw consolidation of an ice-rich soil (active layer) above a permafrost table. The presence of these relict active-layer detachment slides is best known from engineering problems that they have caused, and possibly the best documented is near Sevenoaks in Kent, where road construction reactivated slope instability in sheared periglacial clays (Skempton and Weeks, 1976). Here, careful mapping revealed lobate landslide frontal zones, and boreholes showed at least two generations of slope instability, the most recent of which probably occurred during the Late Glacial Interstadial, after approximately 12 ka. The presence of relict shallow periglacially induced landslides has caused widespread engineering problems elsewhere in southeast England, the Cotswolds, and Lincoln Edge and further north in the Carboniferous mudrocks of Staffordshire and Derbyshire, where the failure of an earth dam at Carsington in 1984 was directly attributable to sheared soliflucted clay that extended beneath the dam foundation (Skempton et al., 1991).

Clay bedrocks are often affected not only by near-surface shallow active-layer landsliding but also by deeper-seated disturbance associated with permafrost growth and decay. Steep shears (Figure 7) extending many meters below the ground surface are interpreted as the result of thaw subsidence during melting of ice-rich permafrost, whereas extensive subhorizontal and less extensive undulose shears at a depth of up to 7 m were explained by Spink (1991) as deep-seated slides within degrading permafrost. It is postulated that upward thawing of the permafrost base due to geothermal heat flux led to high pore pressures as ice-rich permafrost degraded.

Cambering and Associated Structures

Although not widely reported from modern periglacial environments, deep-seated structures observed in Britain and termed cambering have been interpreted as originating under permafrost (Hutchinson, 1991; Ballantyne and Harris, 1994). Cambering occurs where large-scale valley incision has exposed more competent caprocks overlying less competent clay or mudrocks in the valley sides. Caprocks show gravitational extension down the valley sides, forming an attenuating drape, and extension is accommodated by the development of deep fractures termed gulls. Gulls run parallel to the contours and separate intact caprock blocks (Figure 8). Cambering is often associated with the development of anticlinal deformation, termed valley bulging, within the less competent strata beneath the valley axis. The development of cambering is summarized in Figure 8, which identifies the following stages:

1. Initial incision of the river leading to unloading and valley rebound.
2. Permafrost develops, with ice segregation processes increasing ice contents of the frozen clay.
3. Valleyward creep of the frozen clay in response to lateral stresses. This causes extension and initial cambering of caprocks.
4. Permafrost degradation due to large-scale climate warming leads to thaw from the surface downward, enhanced surficial solifluction, and displacement of caprock valleywards over the thaw-softened clays beneath.
5. Thawing of the permafrost base due to geothermal heat flux, thaw consolidation, and high pore pressures within an effectively confined thawed stratum.
6. Lateral extrusion of the thawed clay at the permafrost base leading to compression along the valley axis and pronounced increase in the valley bulge structure.

Most cambering and valley bulging in Britain apparently predates the Devensian glacial stage (Oxygen Isotope Stages 4–2). Hutchinson (1991) postulated that the Anglian stage might have corresponded with the most severe periglacial conditions, with widespread deep permafrost, although this

remains speculative. It seems likely that deep-seated bedrock disturbance took place during more than one Quaternary cold stage.

Periglacial Slope Evolution

An important consequence of the effectiveness of periglacial slope processes is that in the periglacial zone that extended beyond the Pleistocene glacial limits, the landscape is essentially periglacial in origin. Evidence takes the form of hill slope and valley floor deposits and the morphology of the slopes. Kirkby (1987) modeled slope evolution under periglacial conditions (dominated by frost weathering and solifluction). Using evidence from field measurements, he assumed that sediment transport by periglacial solifluction is at least an order of magnitude faster than temperate soil creep. The model predicts progressive decline in valley side gradients and development of rounded summits. Where sediment accumulates in the footslope zone (as in coastal areas during periods of low sea level), an extensive basal concavity develops as slope sediment accumulates. Estimated timescales for this slope degradation are well within the time span of cold stages during the Quaternary.

Introduction

Fluvial deposits in Quaternary sedimentary successions have often been characterized as 'periglacial' when indications exist that they have been deposited under cold-climate conditions. An older, now less frequently used term, mainly in the European literature, is the adjective 'fluvioperiglacial,' which has often been used to denote deposits of small-scale fluvial activity in periglacial environments (Van Huissteden, 1990).

Rivers inside the periglacial zone, just like those outside it, show a wide variety of morphology, a feature that depends on discharge regime, sediment supply, and gradient. In Arctic areas, examples of all the broad classes of river-channel planform, including braided, meandering, and anastomosing, occur (Vandenberghe, 2001, 2003; Vandenberghe and Woo, 2002; Figure 1). The physiographic diversity within the periglacial zone is considerable (French, 2007) and exerts a large influence on river type. Geology and tectonics influence basin bedrock and topography; conspicuous large-scale features are the shield areas of Canada and Scandinavia, the mountain ranges of the Eurasian and western American continents, and the vast sedimentary lowlands of northern Eurasia. Superposed on this is climatic variation, ranging from moist maritime climates with thick winter snow cover, ample summer precipitation and moderate yearly temperature variation, cold and dry desert conditions in the high Arctic, and continental interiors with semiarid conditions and extreme yearly temperature variation, for example, Central Yakutia. This in turn influences vegetation, which ranges from polar desert, tundra, and steppe to boreal forest. Present-day mountain glaciers and ice caps influence river hydrology and sediment supply, while past glaciation may have left behind large sediment stores that still supply sediment to the rivers (paraglacial landscapes; Slaymaker, 2009).

What rivers in the periglacial zone have in common is a discharge regime that is dominated by a pronounced snowmelt discharge peak in spring (Serreze and Barry, 2005), ice cover during part of the year and, in permafrost areas, the interaction with permafrost and ground ice (see section 'Landforms and Processes'). Interaction with aeolian deposition is common, for example, the cold-climate fluvio-aeolian deposits described by Bryant (1983).

Fluvial sediments deposited under periglacial conditions comprise a considerable part of the terrestrial stratigraphic record. Under periglacial conditions, sediment supply tends to be higher than in temperate climates (Vandenberghe, 2003; see below), and interglacials during the Quaternary were short compared to glacials. In fluvial successions in present-day temperate regions, sediments deposited under cold climates therefore tend to dominate. For instance, at

least 87% of the thickness of a 22-m-thick post-Saalian glacial basin fill in the Netherlands contained cold-climate fluvial deposits dating from the Last Glacial (Van Huissteden, 1990).

The effects of anthropogenic climate change are expected to be the strongest in the Arctic (ACIA, 2005), affecting the evolution of periglacial river systems. Many Arctic regions have already experienced increased precipitation and river discharge, and both factors are expected to increase further in the future as a result of climate warming (Walsh et al., 2005). In combination with enhanced permafrost degradation and sediment delivery to rivers, this may cause changes in river morphology. Periglacial river floodplains are also hotspots in the Arctic carbon cycle because they provide sinks for carbon, by storing organic carbon in sediments (e.g., Tarnocai et al., 2009; Van Huissteden, 1990).

Landforms and Processes

Morphology

The terms 'periglacial rivers' or 'periglacial river deposits' may suggest a clearly distinguished fluvial morphology or sedimentary facies linked to periglacial environments. But the variety of forms described above suggests that this is not the case. Vandenberghe and Woo (2002) have therefore argued that 'periglacial rivers' do not exist. By themselves, neither river planform nor sedimentary facies are diagnostic of periglacial environments; for instance, one cannot say that braided-river deposits indicate periglacial conditions. Instead, only smaller-scale morphological or sedimentary features are diagnostic of periglacial environments. One example is beaded drainage (see section 'Permafrost'). A second is hillslope drainage lines in low Arctic (vegetated) tundra, which have a singular appearance (mediated by solifluction), sometimes including recognizable channels, sometimes not. Sufficiently small streams may be strongly influenced by the frozen ground condition. As the river becomes larger, the special thermal conditions appear to matter less.

In all climates, it is the sediment supply relative to transport capacity that determines river morphology (Vandenberghe, 2003; Figure 2). Vandenberghe and Woo (2002) listed braided proglacial sandar, braided rivers, meandering rivers, transitional braided-meandering, anastomosing rivers, and wetland channels. Lunt et al. (2004) presented a depositional model for a braided-anastomosing river. These different types of channel may coexist within the same drainage basin (Figure 1). Between wet and arid cold-climate conditions, a range of fluvial planforms is seen which is similar to that of warmer climates, with braided rivers predominantly in arid conditions. The distinction between braided and meandering rivers is a function of stream power, bank strength, and grain size. With the exception of bank strength, which is influenced by

permafrost (see section ‘Landforms and Processes’), these have no unique link to periglacial conditions.

Present-day anastomosed rivers are not often reported in the literature, but fine examples do exist in periglacial regions (see [Figure 1](#)). A study of the Lena basin rivers showed the importance of log jams and ice jams ([Gautier and Costard, 2000](#)). The annually active main channels occupy a stable position, and avulsion activity is clearly recognizable. Reworking of aeolian material is prominent. A number of delta plains occur on the Arctic coast, for example, the Lena, Mackenzie, and Colville. Examples of Arctic delta morphology and deposits have been described by [Walker et al. \(1987\)](#) and [Hill et al. \(2001\)](#).

Vegetation is a climate-controlled factor, and several authors have attributed a significant role to vegetation in the interpretation of past fluvial succession changes ([Huisink, 1997](#); [Van Huissteden et al., 2001](#); [Figure 2](#)). Shifts in vegetation occur at both warm–cold and humid–arid climate transitions. On the one hand, vegetation determines, sediment delivery – by controlling slope and bank stability – and on the other, it determines discharge – through interception and evapotranspiration. From a theoretical model tested against field data, [Millar \(2000\)](#) concluded that bank vegetation, expressed as a friction angle, exerts a significant and quantifiable control on alluvial channel patterns. [French \(2007\)](#) listed

the availability of coarse-grained bed material in combination with discharge regime as a decisive factor for the presence of braided channels in the north Canadian archipelago. Here, braided rivers may develop into ‘periglacial sandar,’ rivers with all the characteristics of proglacial sandar, but without a glacial sediment source.

Hydrology

The hydrology of periglacial rivers is strongly influenced by the cold climate. There is much uncertainty about values of precipitation and evaporation in the Arctic as the observation network is sparse and the instrumentation for quantifying precipitation and evaporation is subject to uncertainty, particularly in cold climates. Net annual precipitation in the present-day Arctic is typically 150–300 mm, but may reach 1000 mm in the humid North Atlantic sector. Although precipitation over land areas peaks in summer, evapotranspiration in summer is also high. The net precipitation surplus is therefore small or even negative over many Arctic drainage basins; typical values for the precipitation surplus are in the order of 0–200 mm. For the large Eurasian and Canadian river basins (Ob, Yenesei, Lena, and Mackenzie), runoff ranges between 182 mm (Lena) and 396 mm (Ob) basin, while the runoff–

Figure 3 Discharge of the Lena river at Kusur, close to the river delta between 2000 and autumn 2009. Data from Russia Arctic Net/Roshydromet, <http://www.russia-arcticnet.sr.unh.edu/index.html>. The river shows a pronounced spring snowmelt discharge peak.

precipitation ratio ranges between 0.45 and 0.79 (Serreze and Barry, 2005).

The storage of precipitation in the snowpack during a large part of the year and its sudden release in spring strongly influences the annual distribution of the discharge. Moreover, in spring, infiltration into the still frozen ground is restricted (Clark, 1988; Shanley and Chalmers, 1999). Characteristically, the rivers show a rapid increase of discharge in May and June, culminating in a discharge peak in June (Figure 3). The snowmelt runoff takes most of the yearly precipitation, except in wetland basins; the runoff-precipitation ratio may be as high as 0.7–0.8 (Woo, 1990). The importance of snowmelt runoff decreases southward. Concentration of discharge can be expected to occur in regions where snow cover persists for longer than 1 month in 50% of the years (Church, 1988). This includes regions outside the periglacial zone. The magnitude of spring breakup floods depends strongly on weather conditions. With slow melting of the snow in the drainage basin, discharge increase will be less prominent. Usually, however, rainstorms accompany snowmelt and augment discharge. Discharge during snowmelt may display a distinct diurnal pattern (McCann et al., 1972).

Church (1988) distinguished four types of Arctic and subarctic discharge regimes: the subarctic nival regime, the Arctic nival regime, the proglacial regime, and the muskeg (wetland) regime. The subarctic and Arctic nival discharge regimes are characterized by the presence of a pronounced spring flood and decreasing flow in summer. The spring floods may be exacerbated by ice jams (Livingston et al., 2009). In high Arctic watersheds underlain by continuous permafrost, groundwater discharge is virtually absent and rivers are dry in winter. In subarctic river basins, groundwater contributes to the river discharge, in particular in winter, and summer rainstorms may produce flood peaks of higher magnitude than the spring flood. Proglacial rivers derive much of their discharge from melting glacier ice or extensive ice fields and snow banks; the discharge typically continues to rise throughout the summer and is highest in August when glacier ablation is most pronounced. The muskeg discharge regime occurs in poorly drained basins and wetland areas. In summer, high water

retention in lakes, wetland soil, and vegetation contributes to a slow response of the river to rainstorms (Roulet and Woo, 1988).

There are many catchments that do not fit into these four hydrographic categories (Clark, 1988). Superimposed on this general pattern are modifications by local climate and other drainage basin characteristics. Vegetation influences response time of rivers (McCann et al., 1972). In forested regions, evapotranspiration takes a larger part of the summer precipitation. The presence or absence of permafrost is also an important factor. Groundwater contribution ranges from practically zero in continuous permafrost areas to 40% in the discontinuous permafrost zone (Mackay and Løken, 1974). In continuous permafrost areas of the Arctic, only the larger rivers sustain significant winter discharge, particularly if they originate in more southerly areas or lakes (Figure 3). The presence of permafrost also promotes quick response of rivers to storm events and snowmelt (McCann et al., 1972). However, shallow subsurface runoff may also be dominant in peat-covered landscapes as the very conductive surface peat layers offer little attenuation to water drainage (Quinton and Marsh, 1999).

For many rivers in periglacial regions, the nival flood is the major sediment-transporting event (Church, 1988). Pronounced snowmelt discharge causes river channels to have a higher capacity than other rivers with comparable values of annual discharge. This will be expressed in channel dimensions: width, depth, meander wavelength, and gradient. Paleo-discharge estimates of rivers in periglacial regions therefore characterize mainly the nival flood discharge during spring.

Sediment

Sediment delivery to cold-climate rivers is often considered to be high as a result of rapid physical rock weathering, intense slope processes due to the presence of permafrost, and limited vegetation cover in the more arid cold environments. In addition, permafrost degradation may destabilize slopes and increase sediment supply greatly (Bowden et al., 2008). Even in lowlands, mass wasting may be intense. Rapid mass wasting

Figure 4 Left: Active-layer detachment slides on hillslope, Berelegh river, Indigirka lowlands, northeast Siberia. Right: Block slumping along the river bank of the Berelegh river caused by thermal erosion. Photographs by J. van Huissteden.

includes active-layer detachment slides, and thaw slumping (Lewkowicz, 1988; Figure 4). Slow mass-wasting processes include frost creep, gelifluction, and slope wash. Frost creep probably reaches its highest movement rate in the subarctic and higher middle latitudes because it depends on freeze-thaw alternations (Lewkowicz, 1988). The factors that influence gelifluction rate are soil moisture, vegetation cover, slope gradient, and soil grain-size distribution. A well-developed vegetation cover retards gelifluction, while high soil moisture by sufficient precipitation or melt of ground ice enhances it. Materials with a high silt content are most sensitive. Slope wash varies, depending on vegetation, material, and slope hydrology. The concentration of precipitation and runoff in a short time of the year enhances erosion in areas of sparse vegetation (French, 2007; McCann et al., 1972). The presence of large amounts of unconsolidated glacial sediments in catchments that were glaciated during the Pleistocene also enhances sediment supply considerably. Such landscapes in transition are known as ‘paraglacial’ (Church and Ryder, 1972; Slaymaker, 2009).

By contrast, in unglaciated periglacial river basins, measurements of sediment yield do not indicate exceptionally high values. French (2007) summarized total sediment yield from a number of larger periglacial catchments; these range between 0.8 and 85 tonnes $\text{km}^{-2} \text{year}^{-1}$, with partly glaciated Baffin Island as an outlier with 400–790 tonnes $\text{km}^{-2} \text{year}^{-1}$. Data compiled on suspended sediment yield by Bogen and Bønsnens (2003) range between 12 and 82.5 tonnes $\text{km}^{-2} \text{year}^{-1}$ for high Arctic nonglaciated catchments in Svalbard and Norway; higher values up to 200 tonnes $\text{km}^{-2} \text{year}^{-1}$ were measured in Iceland. By comparison, the North American average is 130 tonnes $\text{km}^{-2} \text{year}^{-1}$. Apparently, unglaciated periglacial catchments are modest sediment sources, despite specific factors that potentially contribute to a high sediment yield.

Glaciated catchments, however, produce more sediment. Bogen and Bønsnens (2003) compared an unglaciated and two glaciated catchments in Svalbard, reporting annual suspended sediment yields of 82.5, 359, and 586 tonnes $\text{km}^{-2} \text{year}^{-1}$, respectively. Likewise, sediment transport peak values (5.3, 11.4, and 9.0 g l^{-1}) and averages (0.16, 0.31, and 0.55 g l^{-1}) varied strongly between the catchments. For the unglaciated

catchment, the sediment was also coarser (0.040 mm vs. 0.014 and 0.021 mm). Within glaciated catchments, orders of magnitude differences in sediment yield relate to the thermal regime of the glaciers (cold vs. temperate glaciers) and bedrock erosion susceptibility. Cold-based glaciers (with frozen bed) have lower sediment yields than temperate glaciers (Bogen and Bønsnens, 2003).

Sediment discharge is often largely restricted to the nival discharge peak (e.g., Forbes and Lamoureux, 2005). Observations on the percentages of suspended and bedload sediment transport are limited and point to high interannual variation. Solute transport is relatively minor (Woo and McCann, 1994). Bedload accounts for 77–90% of the annual load of Baffin Island rivers (Church and Gilbert, 1975). Next to the transport processes, the catchment substratum obviously determines these percentages. However, rivers that are fed largely by groundwater (e.g., wetland rivers outside regions with continuous permafrost) tend to have a sediment concentration that is an order of magnitude lower than rivers fed by surface runoff (Woo and McCann, 1994).

Aeolian activity and reworking of wind-blown sediment can also supply sediment to rivers in periglacial regions (e.g., Bryant, 1983). Van Huissteden (1990) and Mol et al. (2000) demonstrated this for Pleistocene rivers in Europe. Periglacial river systems can also act as source areas for loess, which may influence ecosystems distant from the source river (Walker and Everett, 1991). For instance, the widespread occurrence of loess in ‘yedoma’ or ice-complex deposits in eastern Siberia consists largely of floodplain-derived loess.

Boreal and Arctic soils are estimated to store the equivalent of twice the amount of carbon stored in the atmosphere (Schuur et al., 2009). Periglacial floodplains are of specific importance because of their net primary productivity of the vegetation and high carbon sequestration rates in sediments as peat or organic-rich silt and clay (e.g., Van Huissteden, 1990; Zimov et al., 2006). However, emission of carbon and greenhouse gases may also be high. Van Huissteden et al. (2005) reported methane emissions from floodplain wetlands which are of similar magnitude as those of thaw lakes in northern Siberia. In addition, fluvial erosion may remobilize stored carbon.

Figure 5 River icing, Werchojansk mountains, Eastern Siberia. The river itself is an example of a periglacial sandur. Photograph by J. van Huissteden.

Ice

Freezing of rivers during winter raises the water level because of the increased flow resistance created by the ice cover. Near channel obstructions, where flowing water is forced above the ice cover and freezes, river icings or icing mounds (naleds) can develop. These obstructions are most frequent in shallow braided channels (French, 2007). Icings can survive much of the summer melting (Figure 5). In channels with bottom-fast ice, the river beds and banks are protected against scouring during the spring breakup flood as most of the water will initially flow over the ice. By contrast, scouring tends to be more pronounced beneath floating ice, exacerbated by ice floes. The transition to floating ice is associated with a stepwise increase in channel geometry on the Alaskan North Slope (Best et al., 2005).

During spring breakup, ice dams may form, particularly in Arctic rivers with headwaters in the south, where ice melting starts earlier. Ice jams raise flood height of the spring flood and may cause considerable damage (Church, 1988); they are not restricted to rivers in periglacial regions. The high flow velocities, high stage, and mechanical action of moving ice make breakup an important agent of change for river channels, banks, and riparian vegetation (Prouse and Culp, 2003). Near the Yukon River, ice-jam flood deposits can be recognized in its overbank deposits, by the presence of isolated clasts resulting from ice rafting in fine-grained deposits. The deposits indicate a recurrence interval of 25–38 years (Livingston et al., 2009). In Arctic nival rivers, channels become filled with drift snow throughout the winter, which retards flow until the snow becomes saturated with water (Church, 1988).

Permafrost

In areas with ice-rich permafrost, river and floodplain morphology is strongly influenced by permafrost degradation. In smaller headwater streams, 'beaded drainage' is common and is probably the only typical periglacial example of channel planform (Figure 6). The channels exhibit a pattern of small

Figure 6 Beaded drainage channel in a small lowland headwater channel near Kytalyk research station, Indigirka lowlands, Northeast Siberia. The scale bar is 100 m. GeoEye Image, August 2010, ©2008 by GeoEye.

ponds, connected by the channel. The ponds result from thawing where channels cross intersecting ice wedges (French, 2007).

For larger rivers, permafrost also influences river-bank stability. Freezing of unconsolidated river bank and bed material raises its shear strength. Before bank erosion can occur, ground ice in river banks needs to melt, but it is uncertain to what extent this affects channel migration (Clark, 1988). A classic study by Scott (1978) shows a dual effect. During spring breakup, still frozen banks are protected from erosion, but subsequent thawing saturates the banks with water, resulting in destabilization and stronger erosion (see also Figure 4). This may cause high bank erosion rates (Costard et al., 2003). The river water tends to undercut banks by creating thermo-erosional niches, which sometimes can penetrate for several meters below overhanging frozen bank material (Walker et al., 1987). Block slumping is favored by this type of bank undercutting and is a very common feature along lowland rivers in permafrost terrain. On higher river banks, active-layer detachment slides may contribute extra sediment to the river (Figure 4). Higher river banks in unconsolidated frozen sediment tend to show a typical 'baydzherakh' relief, consisting of small hills created by preferential thaw along ice wedges.

The distinction between thaw lakes and floodbasin lakes is not sharp, as floodplain lakes may also show features of expansion by permafrost thaw (**Figure 1**). For example, the majority of lakes in the Mackenzie Delta appear to have formed as thaw lakes and they are partly maintained by permafrost thaw. The lakes become filled in with sediment through over-bank flooding of the river. When the lake is tapped by a river channel, the sedimentation rate increases and the fill may have a delta-like appearance, connected to levees (**Hill et al., 2001**). **Van Huissteden (1990)** documented thaw-lake infilling with fluvial sediment in a Pleistocene succession.

Rivers and lakes in permafrost regions are often underlain by taliks (**French, 2007**). These unfrozen layers or bodies within a permafrost area result from heat transfer from river and lake water to the underlying permafrost; in areas of discontinuous permafrost, the taliks are likely to reach the base of the permafrost. How large the contribution of groundwater flow to the river discharge is, depends on the size and inter-connectedness of the taliks.

Pleistocene Periglacial Environments

Rivers in periglacial environments can be extremely varied, with braided, meandering, straight, and anastomosing channel systems (**Figure 1**). This is also true of cold-climate river sediments in Pleistocene periglacial environments. Additionally there may be episodes of river incision within cold-climate phases. There are currently differences of opinion on the timing of such episodes with respect to climate change during glacial–interglacial cycles.

In sedimentary successions, diagnostic criteria for identifying ‘periglacial’ or ‘cold-climate’ river deposits and forms are not simple, and periglacial conditions during deposition must be deduced from accessory sedimentary features. These are generally periglacial deformation structures, for example, ice-wedge pseudomorphs and cryoturbations. The interpretation of these, however, may be ambiguous, and it is necessary to demonstrate that these features are syndepositional rather than postdepositional. More rarely, features such as preserved thermoerosional niches, frigites (blocks of unconsolidated sediments that have been transported in a frozen condition), or ice-rafted material may be found (**Van Huissteden, 1990**).

On a larger scale, lithology and inferred river-channel plan-form have been used to distinguish Pleistocene periglacial rivers, leading to circular reasoning. Generally, the coarser-grained, supposedly braided-river sediments and fluvial aggradation were assumed to represent deposition during cold climates, while meandering rivers and incision were restricted to warmer climates. This can be traced back to the climatic geomorphology of **Büdel (1977)**. Recent studies in fluvial stratigraphy also refer to this model, to explain the formation of Pleistocene terrace staircases (e.g., **Bridgland and Westaway (2008)** and references therein). However, the link between coarse-grained sediments and cold conditions has been falsified on many occasions (**Vandenberghe, 2003**; see below). In addition, fine-grained deposits occur abundantly in present-day floodplains in periglacial regions (e.g., **Figure 1**, with deposits consisting of silt and fine sand only). Moreover,

climate-controlled terrace successions also occur widely beyond the Pleistocene periglacial zone.

Since the beginning of the 1990s, new conceptual models have contested those simple relationships. The models have focused more on the changing processes at climate transitions, resulting in particular in short episodes of highly increased discharge–sediment ratios caused by the delayed response of vegetation to temperature changes (**Gibbard and Lewin, 2002**; **Vandenberghe, 1995**). The preservation potential of former floodplains, however, seems to be lower at warm-to-cold transitions than at cold-to-warm ones (**Vandenberghe, 2008**). This may explain the apparent rarity of interglacial terraces in Pleistocene terrace staircases and thus the equal number of terraces and glacial–interglacial cycles (and not a twofold higher number of terraces). Moreover, fluvial system changes may depend on the time scale. Many authors have assumed that climate change translates itself directly into fluvial depositional changes. However, **Van Huissteden et al. (2001)** have shown that this is not always the case, particularly on the time scale of the millennial climate changes that occurred during glacial climates of the Quaternary.

River sedimentation in cold conditions is believed to be especially sensitive in regions where rivers have been close to metastable equilibrium or thresholds (**Kasse et al., 2003**). Expression of river activity in sedimentation is also related to local conditions. **Rose and Boardman (1983)** emphasized the importance of relief contrast and the rate of sediment supply to the channel. Properties such as vegetation cover, particle size of the transported material, and gradient were mentioned by **Vandenberghe (1995)**, **Kasse (1998)**, and **Mol et al. (2000)**. Consequently, delayed responses to climatic conditions may provoke varying fluvial processes, sediments, and patterns depending on these local conditions. Lastly, rapid climate change may have caused conditions for which a present-day analog is absent. For instance, the frequent and large amplitude climate variations of Marine Isotope Stage (MIS) 3 contrast with the relatively stable Holocene. **Van Huissteden and Kasse (2001)** attributed rapid fluvial basin filling during the Middle Weichselian in Western Europe to frequent cycles of permafrost aggradation and degradation related to the MIS interstadials.

Two examples illustrate the variety of Pleistocene cold-climate fluvial environments. First, in southern Britain, lowland river terrace sediments predominantly consist of waterlain, sorted gravel and sand (**Figure 7**) occurring in suites of sedimentary structures that indicate deposition under broadly similar fluvial conditions. The most common facies is massive or horizontally crudely bedded gravel (**Figure 8(a)**). The clasts have a great size range, their form determined by local source lithologies, but the most frequent are medium to fine gravel (1–30 cm). Larger clasts do occur and may reach over 50 cm, but these are rare. Periglacial conditions are indicated by cryoturbation structures, ice-wedge pseudomorphs, physically weathered materials, and (rarely) frigites.

The gravels often show poorly developed horizontal bedding and are generally matrix supported and matrix rich. Clast-supported gravel is common, particularly in the coarser particle sizes. Interstices are filled with silt, sand, and granules. Secondary clay may also be present. Individual gravel units are typically up to ca. 90–125 cm thick but are frequently superimposed to produce multistorey units of greater thickness. Laterally, the

Figure 7 Schematic section of coarse-grained terrace sediments in lowland Britain. Single- or multistorey, matrix-rich gravels rest on an erosional substrate base. These may be capped by colluvial and aeolian sediments. Inset section showing sedimentary structures and periglacial features is based on [Briant et al. \(2004\)](#).

gravel units may be persistent and can be traced across exposures for over 30 m. They usually rest on an erosional base and often occupy channels cut into the underlying substrate.

'Channel' scours with erosional bases within gravels may be filled by interbedded sands and gravels at a range of scales. Some probably represent the truncated lower levels of channel fills abandoned by switching, other smaller ones to scouring related to migrating bedforms. Sandy facies occur as lenses and occasionally as massive sand beds. Finer materials occur infrequently as beds of silty clay, clayey silt, and organic sediment, either in channel fills or in former floodplain depressions. Organic materials include both autochthonous aquatic plants and animal fossils and allochthonous material washed in during flood events from vegetated stable tracts and neighboring slopes. Occasionally there are vertically accreting fining-upwards sequences.

Adjacent to contemporaneous valley sides, lenticular wedge- or tongue-shaped bodies of locally derived diamicton are often found, both interstratified with and overlying fluvial sediments. These indicate a dominance of catchment-wide slope-sediment contributions which may contrast to point-sourced glacier-melt sediment inputs into ice-marginal river systems. Rivers in former periglacial environments commonly only occupied part of the valley bottom at any particular time, and large areas of alluvial plains became temporarily stable and colonized by vegetation. During exposure, these surfaces experienced subaerial weathering, and ice-wedge polygons, and cryoturbation developed in favorable localities, particularly on higher stable tracts. Infill and truncation of ice-wedge casts, together with disturbance, truncation, and burial of valley-side mass-flow deposits are found, in combination

with abandoned channel fills. Extensive planar erosional surfaces have been attributed to truncation of fluvially inactive areas, raised slightly above the active areas of the river by large-scale channel migration. The association of truncated infilled ice-wedge casts and other periglacial phenomena, channel fills, and earlier sediments beneath such surfaces could be interpreted as a normal feature of cold-climate autogenic reworking ([Figure 8\(a\)](#) and [8\(b\)](#)).

The assemblage of sedimentary facies and structures present in British Pleistocene river terraces closely approximates those of braided-river environments (e.g., [Bryant, 1983](#)). This is also true of extensive areas of central and eastern Europe. The consistent association with climatic indicators such as ice-wedge casts, solifluction deposits, frozen block transport, and cryoturbation structures suggests deposition under a predominantly periglacial regime.

A second example consists of river sediments in European lowland basins, for example, in the Netherlands, northern Germany, and Poland ([Figure 9](#)). These sediments consist of alternating beds of coarse sand with varying amounts of gravel, fine sand, silt and clay, and organic beds (peat and gyttja). Usually, the beds have been periglacially disturbed and show a large range of cryogenic structures, including ice-wedge casts, frost fissures, and cryoturbations. The fine-grained beds indicate alluvial plains with well-developed marshy flood basins. These flood basins may have been occupied by shallow lakes for much of the year. These lakes may have developed partly as thaw lakes, as in many contemporary Arctic environments.

In addition, sand was deposited in overbank environments. Sedimentary structures in many sand beds indicate deposition

Figure 8 (a) Crudely stratified gravel at Block Fen, Cambridgeshire, England; prominent ice-wedge cast at left side. (b) Cryoturbated gravel and fine organic sediment at Thrupp House Farm, near Abingdon, Berkshire, England. Photographs by P.L. Gibbard.

Figure 9 Schematic section and block diagram of fine-grained fluvial deposits of Middle Weichselian age in northwest European lowlands, based on the Dinkel river valley fill in the eastern Netherlands (Van Huissteden, 1990). The valley fill shows two distinct fluvial facies, occurring contemporaneously: anastomosing-meandering rivers with extensive floodbasin deposition (left) and anastomosing-braided rivers with fluvio-aeolian overbank deposition (right). The coarsest material in the deposits is coarse sand with minor amounts of gravel.

in levees and extensive crevasse-splay systems that prograded to shallow lakes or marshy floodbasins. Periglacial features including ice-wedge casts and involutions occur abundantly at the top of these sand bodies, underlying the silts and peats, which suggests that permafrost degradation may have created the depressions in which the fines were deposited; lacustrine sediments (gyttja or laminated silts) are common. Channel deposits form a minor component of alluvial sediment assemblages, suggesting minor lateral channel migration. Channels were stabilized by abundant riparian vegetation and cohesion of the fine-grained beds. Channel migration occurred mainly by avulsion (Figure 9). The large volume of overbank deposits, sedimentary structures, and geometry of the channel deposits suggest anastomosing patterns, with more than one active channel on the floodplain, separated by marshy flood basins (e.g., Mol, 1997; Van Huissteden, 1990).

Facies variations do occur. A lateral transition toward fluvio-aeolian sands has been described from the Dinkel valley

in the Netherlands (Van Huissteden, 1990; Figure 9). In this fluvio-aeolian facies, the silty overbank deposits have been partially reworked into aeolian sand-sheet deposits. The aeolian deposits in the fluvio-aeolian facies are assumed to have been derived from periodically dry channel beds and bars. In continental environments, fluvially deposited, but reworked aeolian materials may form a very important contribution to sediment assemblages.

Future Perspective

Future climate warming is expected to be strongest in the Arctic (ACIA, 2005). Consequently, many periglacial rivers today are systems in transition. Permafrost zones will shift northward, and warming will tend to increase active-layer thickness and talik extent, increasing groundwater contribution to the discharge (Bense et al., 2009; Woo and McCann,

1994). Second, expansion of thaw ponds and lakes will increase water storage in catchments. Modeled thaw-lake expansion in response to future warming indicates a threefold increase in lake area for northern Siberia in the next century, which is subsequently reduced by lake drainage (Van Huissteden et al., 2011).

Climate models also indicate a general increase of precipitation over the large Arctic drainage basins, resulting in an increased precipitation surplus as well (ACIA, 2005). This precipitation increase is concentrated in winter. For the summer, the tendency in precipitation surplus is less certain; particularly for evaporation, the models show contradictory results. The increased winter precipitation will induce higher spring discharge peaks and enhance permafrost degradation (ACIA, 2005). In the Eurasian Arctic, the annual discharge from the six largest rivers increased by 7% between 1936 and 1999 (Peterson et al., 2002).

Permafrost degradation, in turn, may increase slope instability, and sediment and nutrient delivery to rivers (Bowden et al., 2008). On the other hand, the extent of snow cover has decreased since approximately 1980. Climate models predict reductions between 9% and 18% by the end of the twenty-first century. These reductions are most prominent in the spring and autumn months, resulting in an earlier spring discharge peak and less prominent nival discharge. Spring breakup has shifted to earlier dates during the last century for many Arctic rivers (ACIA, 2005).

A further effect of Arctic warming is vegetational change. Throughout the Arctic, an expansion of shrub vegetation in tundra areas is reported (e.g., Tape et al., 2006). This affects not only hillslopes, but also river beds and banks; Tape et al. (2006) identified shrub expansion in braided-river beds. This may result in a complete transformation of rivers, by affecting bed morphology, bank stability, channel and floodplain roughness, slope stability, and sediment delivery, and by increasing evapotranspiration.

Woo and McCann (1994) stressed the complex response of (fluvial) environmental processes as a result of climate warming. Anisimov et al. (2008) reported model experiments on the effects of increasing discharge for rivers in northern Russia, resulting in a tendency toward multithreaded channels. However, the effects of other changing factors such as increasing vegetation result in large uncertainty. Apart from the development of simulation models, spatial and climatic analogs may be applied for predictions of future hydrological and fluvial consequences (Woo, 1990). However, caution must be exercised in the use of poleward shifting climatic zones to predict changes in present-day periglacial rivers because of nonanalog and transient effects such as delayed vegetation migration.

Rock Weathering

J Murton, University of Sussex, Brighton, UK

© 2013 Elsevier B.V. All rights reserved.

Angular, shattered rock is abundant in many cold regions, where it forms a major source of gravel-size clasts to hillslopes, rivers and glaciers. The shattering has often been attributed to frost action, particularly *in situ* freezing and expansion of water trapped in spaces within rock. However, increasing evidence suggests that ice segregation is a major process in fracture of fine-grained and porous rock, and that other mechanical, chemical and biological weathering processes contribute significantly to rock weathering in periglacial and permafrost environments. This article focuses on rock weathering processes, particularly mechanical ones, about which there has been much uncertainty concerning the role of frost. It also summarizes data on weathering rates and products.

Mechanical Weathering Processes

Mechanical weathering processes in periglacial and permafrost regions result from freezing and thawing of water (frost weathering; reviewed by Matsuoka and Murton, 2008) and from changes in unfrozen water content or temperature. Two processes of frost weathering can be distinguished (volumetric expansion and ice segregation), as can two processes that may be well developed in periglacial regions but are not confined to them (hydration shattering and thermally induced stress).

Azonal processes such as salt weathering and pressure release are not discussed, although they may be widespread in polar deserts, maritime regions and recently deglaciated mountains.

Volumetric Expansion

Upon freezing, water expands in volume by 9%. If the water completely fills spaces in rock and freezes *in situ*, then, theoretically, at a temperature of $-22\text{ }^{\circ}\text{C}$ it can exert a maximum tensile stress of 207 MPa in a rock strong enough to withstand it, as the water becomes ice. This ice-induced stress is easily great enough to fracture any rock because the maximum tensile strength of rock is one or two orders of magnitude lower than 207 MPa. Furthermore, the other conditions of (1) a high degree of rock saturation to avoid compression of air, (2) rapid cooling rates to allow *in situ* freezing of water within a closed system, and (3) freezing to temperatures below $-5\text{ }^{\circ}\text{C}$, seldom coincide at sites supposed to favor frost weathering, such as bergschrunds, snow patches and rockwalls (McGreevy, 1981). Thus, the dominant role in frost weathering often attributed to volumetric expansion has been questioned (Walder and Hallet, 1985, 1986). This process, however, does appear to operate within a few centimeters of the surface of rocks whose pores or cracks are water-filled (or nearly so) and subject to rapid freezing, resulting in prying away of mineral grains and

rock flakes. At a larger, outcrop scale, volumetric expansion within existing water-filled joints in bedrock can widen joints and heave bedrock.

A second way in which volumetric expansion may break up rock is by hydrofracture. Just as the expansion of water freezing within saturated pores in sand or gravel expels water ahead of the freezing front, so will does freezing of a rock that is saturated (or nearly so) and contains relatively large pores (e.g., medium- to coarse-grained sandstones). Likewise, freezing of saturated rock with pores small enough to favor cryosuction and ice segregation can instead expel water if freezing is sufficiently rapid (Walder and Hallet, 1985, 1986). If the water cannot drain away as quickly as it is expelled, pore water pressure may rise sufficiently to deform or hydrofracture the rock. Therefore, intact rock may potentially hydrofracture during rapid inward freezing of boulders (causing the rock to burst; Lautridou, 1988) or, perhaps, during two-sided freezing of an active layer. Nonetheless, hydrofracture of rock during freezing remains to be investigated in detail, particularly its relationship with bedrock heave by volumetric expansion in water-filled joints in the active layer (Dyke, 1984).

At the scale of sand-sized particles, quartz disintegrates more readily than feldspar, contrary to its behavior in temperate and warm-climate conditions (Konishchev and Rogov, 1993). A substantial body of experimental data indicates that quartz sand subjected to numerous freeze–thaw cycles tends to break down more readily than feldspar and produce finer particles, within the 0.05- to 0.1-mm (silt) size fraction. The causes of breakdown, inferred in part using scanning electron microscopy, are attributed to (1) the wedging effect of ice forming in microcracks, which makes them widen and lengthen, and (2) freezing of water within gas–liquid inclusions.

Ice Segregation

A theoretical model of rock fracture by ice segregation attributes the fracture to progressive microcracking as a result of growing ice lenses (Walder and Hallet, 1985, 1986). Ice segregation occurs when liquid water migrates through a porous medium toward freezing sites where lenses of ice grow, segregated from adjacent mineral particles. The migration results from temperature-gradient-induced suction gradients in freezing or frozen ground. As porous soil or rock freezes and cools, a suction (dP_w) develops in the liquid water held in capillaries and adsorbed on the surfaces of mineral particles (Williams and Smith, 1989):

$$dP_w = -dTl/VT \quad [1]$$

where dT is the lowering of the freezing point, l is the latent heat of fusion, V is the specific volume of water, and T is the absolute temperature. Equation [1] indicates that a temperature drop of $1\text{ }^{\circ}\text{C}$ induces a ‘cryosuction’ of 1.2 MPa (12 atm).

Suction gradients drive liquid water toward freezing sites. The water nourishes ice lenses at sites where release of latent heat from freezing of soil water balances loss of soil heat toward the ground surface or permafrost table. While this balance persists, ice lenses continue to grow on the cold side of a partially frozen fringe, with the lenses aligned perpendicular to the direction of heat flow. However, when heat loss exceeds heat supply, the fringe cools, which promotes pore-ice formation. This in turn reduces the permeability of the fringe, effectively shutting off the water supply to the ice lens, and thus the fringe advances through the soil until a new thermal balance is reached between heat supply to and heat loss from the cold side of the fringe, at which point a new ice lens develops (Williams and Smith, 1989). In this way, the fringe episodically moves, producing a rhythmic banding of segregated ice and pore ice (Figure 1). Detailed discussions of the microphysics of the ice-segregation process and of the spacing and thickness of ice lenses are given by Rempel (2007, 2011).

There is increasing evidence that ice segregation is an important cause of fracture of moist, porous rocks (Matsuoka, 2001; Matsuoka and Murton, 2008), just like it is in the fissuring and heave of frost-susceptible soils. Unlike the stringent conditions needed for volumetric expansion to fracture natural rocks, the conditions needed for ice segregation (slow rates of freezing or sustained subzero temperatures in moist, porous fine-grained rock) are common in natural bedrock. Laboratory experiments have demonstrated that ice segregation can fracture fresh blocks of tuff and sandstone under constant temperatures and temperature gradients (Akagawa and Fukuda, 1991; Hallet et al., 1991), and simulation of natural uni- and bidirectional freezing regimes resulted in fracture of fine-grained, porous rock by ice-lens growth in near-surface permafrost and seasonal frost (Figure 1; Murton et al., 2001; 2006). The fractures and ice lenses resemble those in arctic permafrost and provide an explanation for some Ice Age weathering profiles in the mid-latitudes. Ice segregation and the resulting frost cracking may also contribute to a frost “buzzsaw” mechanism for erosion of some mountains, for example the eastern Southern Alps of New Zealand (Hales and Roering, 2009).

Figure 1 Segregated ice within artificial permafrost developed in a siliceous chalk (Tuffeau). Scale in centimeters. Satellite cracks have begun to develop beneath the main crack. The rock between the ice lenses contains pore ice.

Hydration Shattering

Hydration shattering results from the pressure exerted on the walls of pores with diameters of a few micrometers or less by water molecules adsorbed onto the surfaces of clay particles. Because water comprises polar molecules, the positive charge of the two hydrogen atoms ($2H^+$) at one end of the molecule is attracted to the negative charge of clay surfaces, leaving the negatively charged oxygen atom (O^{2-}) at the other end pointing away from the surfaces. Where the pores between clay particles are large ($>5\ \mu m$ diameter) and filled with ‘bulk’ (nonadsorbed) water, projecting oxygen atoms on opposite sides of the pore are too far apart for the similar negative charges to repel each other. However, where the pores are small ($<5\ \mu m$ diameter), they are dominated by adsorbed water, which is difficult to freeze, rigid, and capable of exerting force against pore walls. In such pores, adjacent negatively charged O^{2-} atoms repel each other. As the temperature falls below $4\ ^\circ C$, the adsorbed water expands; the degree of alignment (ordering) of water molecules increases (and hence the repulsive force between negative charges at the free ends of adsorbed layers); and the relative humidity increases, supplying water to the adsorbed water layer. Rock failure is attributed to fatigue due to expansion and contraction as water molecules are sorbed and desorbed on the adsorbed layer. Large temperature changes and cycling within the freezing and thawing range may promote sorption and desorption and, therefore, rock fracture (Hudec, 1973).

Laboratory experiments suggest that hydration shattering at subzero temperatures can be effective in breaking down clay-rich rocks (Dunn and Hudec, 1966). It is unclear, however, whether this process is effective in fracturing coarser-grained rocks or in producing angular fragments of sound rock that are commonly observed in alpine and polar regions (Washburn, 1979, p. 74).

Thermally Induced Stress

Rock has a tendency to expand on warming and to contract on cooling to an amount determined by the thermal coefficient of linear expansion of its constituent minerals. The coefficient denotes the relative change in length resulting from a $1\ ^\circ C$ temperature change—approximately $1\text{--}12 \times 10^{-6}$ length $^\circ C^{-1}$ for common rock-forming minerals. If we consider a body of intact rock that is laterally extensive and subjected to surface cooling, the rock surface is unable to contract freely in a horizontal direction because of (1) the physical constraints imposed by the lateral continuity of the rock surface and (2) the thermal stability of the underlying rock. Thus, the rock resists thermal contraction in a horizontal direction and, as a result, experiences tensile stress in this direction. The stress can be relieved by either fracture or creep of the rock—the same responses to tensile stress as those exhibited by winter cooling of frozen soil in permafrost regions.

Rock fracture may result in two situations, determined by the magnitude and frequency of thermally induced stresses. Repetitive, low-magnitude stress events, each one insufficient to cause immediate failure of the rock, may collectively cause failure over time (thermal stress fatigue), whereas a single, high-magnitude stress event generated by very rapid

temperature change ($>2^{\circ}\text{C min}^{-1}$) may trigger cracking immediately if tensile stress exceeds tensile strength (thermal shock). The temperature changes believed to favor rock fracture typify high-altitude and high-latitude regions, where large inputs of solar radiation may occur when air temperatures are below 0°C . During such times, rock surfaces often have above-zero temperatures until cloud blocks out solar radiation and the surface temperature plummets to many degrees below 0°C . Frequent and sometimes rapid changes in net radiation at rock surfaces produce frequent and rapid temperature changes as well as steep temperature gradients in the outermost centimeters of rock—conditions that favor thermally induced stress.

Centimeter-scale polygonal crack patterns observed in rocks of the High Andes and ice-free regions of Antarctica have been attributed to such stress (Hall, 1999), which seems reasonable in these extremely dry (ice-poor) environments. The efficacy of this weathering process, however, is probably limited to the outer millimeters or few centimeters of the rock surfaces because surface temperature waves are exponentially dampened with depth (Williams and Smith, 1989).

Chemical Weathering Processes

Although chemical weathering in periglacial regions has often been regarded as of minor significance (because of low temperatures), there is increasing evidence that contests this view (Pope et al., 1995). In alpine periglacial regions, dissolution of mineral grains commences soon after fresh bedrock is exposed to surface or near-surface environments (Dixon and Thorn, 2005). In the Colorado Rocky Mountains and the Jotunheimen mountains of southern Norway, for example, solutional processes promote disintegration of coarse debris. Dissolution of quartz, feldspars and micas within the debris results in an absolute loss of alkalis (Na and K), alkali earths (Ca and Mg), and silicon (Si) relative to resistant chemical species (Fe, Al and Ti). In Rapp's (1960) seminal study of mountain slopes in Karkevagge, arctic Sweden, solution was identified as the single most important transport mechanism. Recent work, summarized by Thorn et al. (2001), supports the importance of chemical weathering at this locality, emphasizing that pyrite-rich bedrock oxidizes to produce sulfuric acid, in turn favoring dissolution of muscovite and solution of calcite.

Oxidation of iron-bearing minerals produces reddish-colored weathering rinds on bedrock or clast surfaces. Even the dominantly mechanical process of *grus* formation on a nunatak in the Juneau Icefield, Alaska, is associated with measurable chemical weathering as biotite transforms to vermiculite, which is accompanied by a loss of K and Mg and by oxidation of Fe. From such studies, it is clear that the chemical weathering processes in alpine periglacial regions are similar to those in mid-latitude environments (Hall et al., 2002; Dixon and Thorn, 2005). This conclusion is consistent with the observation that the solute contents of alpine streams (ions dominated by Ca, Si and, sometimes, Mg, with smaller abundances of Na, K or Mg; anions typically dominated by bicarbonate and, in some locations, sulfate) are generally similar to those in other climatic regions. Solute concentrations in alpine streams, however, are typically lower than those in other environments, probably

because exposed bedrock rather than thick regolith dominates most alpine basins, thus limiting the opportunities for chemical weathering by slowly percolating groundwater.

Chemical weathering also takes place within sediment in arctic and sub-arctic active layers. As ice within active layers thaws in summer releasing water into the soil, weathering of labile minerals takes place above the water table. Oxidation of sulfides (e.g., pyrite) and solution of carbonates (e.g., siderite) has been inferred from studies of heavy minerals in paleo-active layers in Canada, with distinct mineralogical differences sometimes found between sediment that has thawed in the active layer and underlying sediment that has remained frozen within permafrost. Differences in clay mineralogy and soil color (the presence or absence of oxidation) have also been noted across some thaw unconformities (Burn et al., 1986), providing further evidence of chemical weathering in permafrost regions.

Biological Weathering Processes

There is a growing appreciation of the importance of biological and biochemical weathering in cold regions (Hall et al., 2002). These processes involve a range of rock-colonizing organisms (e.g., bacteria, fungi, lichens, mosses and trees) that exert physical stresses and/or induce chemical processes (e.g., chelation, oxidation and reduction). Tree roots, for example, can pry apart jointed rock on rocky mountain slopes, whereas micro-organisms living within or beneath rocks in polar deserts may cause both the removal and precipitation of minerals at or close to the rock surface. For example, lichens growing on and within rocks in the dry valleys of Southern Victoria Land, Antarctica (Friedmann, 1982), and the Jotunheimen mountains of southern Norway (McCarroll and Viles, 1995) cause exfoliation of the rock surface as a result of solubilization of cement and by mechanical processes involving penetration of hyphae into the rock and freeze-thaw-induced expansion and contraction of the thallus of endolithic lichens. Likewise, fungal growth can induce biochemical processes that appear to be the main agents of weathering rind development on boulders on Icelandic moraines (Etienne, 2002).

Weathering Rates

Weathering rates in periglacial regions are poorly known because weathering tends to be a slow, subsurface process and it is often difficult to measure fracture growth and to date weathered surfaces. Occasionally, explosive shattering or 'bursting' of boulders exposed to cold air temperatures in the arctic and sub-arctic has been inferred from descriptions of sounds resembling a rifle discharge and from angular rock fragments scattered over snow around a broken boulder. These observations suggest that such shattering results from an explosive release of tensional stresses, although whether these stresses result from hydrofracturing, thermal shock or ice segregation is often unclear (Mackay, 1999). By contrast, much slower rates of crack propagation seem to be characteristic of ice segregation and bedrock heave (Murton et al., 2001, 2006), consistent with slow migration of unfrozen water toward freezing sites (Walder and Hallet, 1985, 1986).

The rates of weathering rind formation in mid-latitude alpine environments appear to be comparable to, or greater than, those in non-alpine environments, with 6- to 45-mm thick weathering rinds forming in 10,000–20,000 years in the Colorado Alpine compared to rates of ~ 0.18 mm over the same period from non-Alpine California (Dixon and Thorn, 2005). In Lapland, weathering rinds ~ 1 -mm thick can develop in 5 years, indicating how rapidly chemical weathering commences. However, such growth rates may decay exponentially through time, making it difficult to extrapolate from short-term field experiments to long-term natural rates.

Chemical erosion (mass removal) and chemical denudation (surface lowering) rates in alpine settings are often substantial (Dixon and Thorn, 2005). In mid-latitude alpine periglacial environments of Scandinavia, North America and central Europe, rates of chemical erosion range from ~ 9 to $100 \text{ t km}^{-2} \text{ year}^{-1}$, comparable to the global average for all rock types ($45 \text{ t km}^{-2} \text{ year}^{-1}$) and to values from the Amazon and Mississippi rivers ($35\text{--}45 \text{ t km}^{-2} \text{ year}^{-1}$). Moreover, chemical erosion rates in alpine settings often substantially exceed mechanical erosion rates. Rates of chemical denudation measured in alpine Colorado and Scandinavia are $\sim 0.2\text{--}5$ mm per 1,000 years (higher in carbonates than crystalline rocks), similar to those in other montane and polar environments. In general, the denudation of alpine landscapes is strongly influenced by chemical processes because of their strong coupling to the drainage network, facilitating rapid and effective removal of solutes from the drainage basins (Dixon and Thorn, 2005).

Steep rocky slopes in periglacial regions undergo headwall retreat as a result of weathering and rockfall. Estimates of rock-wall retreat rates in Holocene and present-day alpine environments have an overall mean of 1.1 m ka^{-1} , which is distinctly greater than that of 0.3 m ka^{-1} from arctic environments (Table 1). As indicated by the large standard deviations in Table 1, the retreat rates are highly variable, in part due to differences in lithology, microclimate and measurement techniques. Although such rates must also vary through time, simple extrapolation of the overall means during the Holocene (past 11,500 years) indicates, to a first approximation, net rockwall retreats of ~ 3.5 m in arctic environments and ~ 12.5 m in alpine ones. The implications of such rates must be borne in mind before carrying out cosmogenic dating of such slopes.

Weathering Products

The products of periglacial weathering vary substantially in scale and nature. At the microscale are silt-sized particles,

often quartz, formed within cryogenic regoliths. Such particles probably constitute important sources of silt to periglacial rivers and eolian systems and, during the Pleistocene, to the ice-rich yedoma deposits of Beringia—a major archive of Quaternary environmental change. Within periglacial soils and regoliths, ferromagnesian minerals are often oxidized on grain surfaces and along cleavage planes, as is common in alpine regions (Dixon and Thorn, 2005). Disaggregated bedrock material, consisting of sand- to pebble-sized particles and

sometimes clay (grus), is common in periglacial areas of crystalline rocks. Although grus is attributed primarily to mechanical weathering, strong reddish brown colors indicative of oxidation are sometimes present (Figure 2).

Weathering rinds (~ 0.5 – 45 -mm thick) are often developed on bedrock or coarse debris. The rinds generally have a reddish-colored outer surface (due to oxidation of iron-bearing minerals) underlain by a lighter colored bleached zone. Some rinds have chemical rock coatings; in the Scandes Mountains of

Swedish and Norwegian Lapland, for example, such coatings are dominated by Fe, Si, Al, Ca and heavy metals.

Pebble- to boulder-sized rock fragments often litter hill-slopes in rocky periglacial regions, forming gravelly surfaces (Figure 2) and bouldery blockfields (Figure 3(a)). Many, but not all, of these fragments are angular. However, occasionally angular and rounded clasts occur side by side (Hall et al., 2002) as a result of lithological differences influencing the style of weathering (e.g., rock fracture versus granular

Figure 4 Weathering profiles formed by ice segregation within bedrock permafrost. The profiles comprise mainly horizontal to subhorizontal fractures that delimit angular, platy fragments of rock, with the overall fracture density decreasing with depth. Pen for scale in (d) (From Murton JB (1996) Near-surface brecciation of Chalk, Isle of Thanet, southeast England: A comparison with ice-rich brecciated bedrocks in Canada and Spitsbergen. *Permafrost and Periglacial Processes* 7: 153–164, reproduced with permission).

disintegration). The same variation in angularity of form appears to occur in weathering forms, which range from rounded pits, pans, grooves and tafoni to angular rockwalls. Even within the same small region, tors may vary in shape from rounded to angular (Figure 3).

Fractures in clasts and bedrock can result from a variety of mechanical weathering processes. Fractures formed by ice segregation are usually more or less parallel to the rock surface (i.e., cooling surface; Mackay, 1999), whereas those formed by hydrofracture or thermal shock may have a variable orientation, often perpendicular to the rock surface.

Weathering profiles comprising fractured (brecciated), porous bedrock can result from ice segregation within permafrost and seasonally frozen ground. The profiles are characterized by pebble- to cobble-sized rock fragments that are tabular, angular to subangular, aligned more or less parallel to the cooling surfaces (ground surface and permafrost table), and interspersed with ice lenses (Figure 4(a) and 4(b); French et al., 1986). The rock types include limestones, fine-grained sandstones and shales, all of which contain an interconnected network of fine pores through which unfrozen water can migrate toward the upper meters of permafrost. Relict profiles are common in limestones and mudstones in areas of former Pleistocene permafrost, such as southern England and northern France (Figure 4(c) and 4(d); Murton, 1996), and were probably a significant influence on periglacial landscape evolution, supplying rock fragments to hillslopes and rivers.

In the case of weathering profiles showing joints and fractures in low-porosity crystalline bedrock beneath autochthonous blockfields, ice segregation is unlikely. A more feasible process of fracture growth and clast supply is that of frost wedging. It is hypothesized that bedrock disintegration at the weathering front beneath certain autochthonous blockfields is mainly due to frost wedging that enlarges pre-existing stress-release joints at the base of a water-saturated active layer above permafrost (Ballantyne, 2010; Goodfellow et al., 2008). This hypothesis remains to be tested by field monitoring or laboratory experiments.

Conclusions

Of the mechanical weathering processes known to occur in periglacial and permafrost regions, only ice segregation is at present strongly implicated as a widespread and volumetrically important cause of rock fracture. Because fine-grained and porous bedrock is frost-susceptible, ice segregation is a major cause of both soil fissuring and bedrock fracture. Ice segregation is most common in the active layer and near-surface permafrost and in seasonally frozen ground in nonpermafrost regions; thus, the resulting fissures and fractures tend to be most common in the upper meters of soil and bedrock. Additional mechanical weathering processes certainly occur in some cold regions, but their extent and geomorphic significance remain to be clearly established.

It is clear that both chemical and biological weathering processes are widespread and important in many periglacial and permafrost regions. However, their main contribution to landform development, at least in alpine and Antarctic regions, seems limited to small-scale forms (e.g., pits, pans, grooves and

tafoni) and to microscale features, such as rinds and coatings. It is also clear that mechanical, chemical and/or biological processes in cold regions often operate concurrently at the weathering boundary layer (Pope et al., 1995). The combined effects of frost and salt near periglacial coasts, for example, can promote rock disintegration, whereas interactions of mechanical and chemical weathering processes often contribute to the formation of weathering rinds (Thorn et al., 2001). Even in the polar deserts of Antarctica, a variety of weathering processes interact (Guglielmin et al., 2005). Indeed, chemical weathering may occur wherever liquid water is present; thus, dissolution at the ends of microcracks (stress corrosion cracking) might enhance crack propagation during ice segregation. In turn, ice segregation prepares fresh mineral surfaces for chemical weathering (Hoch et al., 1999), indicating feedbacks between weathering processes.

Permafrost and Glacier Interactions

R I Waller, Keele University, Newcastle-under-Lyme, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

In terms of their extent and seasonal persistence, glaciers and permafrost constitute the two most important elements of the global cryosphere. Combined, they currently cover an area of over 35 million km², and they were more widespread still during Quaternary glacial periods. However, in spite of their extent and contiguity in both modern and Pleistocene environments and their responsiveness to climatic variations, their potential for active interactions has traditionally received little attention. First, glaciers and permafrost are often viewed as being mutually exclusive because thick ice insulates the land surface from the prevailing climatic conditions. Second, key processes such as basal sliding and subglacial sediment deformation are often considered inactive beneath cold-based ice. Third, with most work in glacial geomorphology and geology undertaken in areas characterized by hard bedrock (e.g., the Laurentian Shield) and/or glaciated by warm-based ice, there has been little need to consider the interaction of cold-based glaciers with permafrozen sediments. A growing body of research, however, has challenged these assumptions by recognizing that, in certain circumstances, glaciers and permafrost can couple and interact and that these interactions are more extensive and glaciologically more significant than was previously thought (Astakhov et al., 1996; Bennett et al., 2003; Cuffey et al., 1999, 2000; Echelmeyer and Zhongxiang, 1987; Murton et al., 2004).

This article considers the key characteristics, formation, and likely extent of glacier–permafrost interactions, their influence on the dynamic behavior of glaciers and ice sheets, and their geomorphological and geological signatures. Specific emphasis is placed on sedimentary sequences and landforms in lowland environments influenced by continental ice sheets as these tend to have a greater preservation potential than those in uplands and are, therefore, the situations most commonly examined in Quaternary paleoglaciological reconstructions. Reviews focusing on glacier–permafrost interactions in high mountain areas are provided by Etzelmüller and Hagen (2005) and Haeberli (2005), and climate-change impacts in glacier and permafrost regions are reviewed by Haeberli and Burn (2002).

The Nature, Formation, and Extent of Permafrost in Glacial Environments

Permafrost is defined as “ground (i.e., soil and/or rock) that remains at or below 0 °C for at least two consecutive years” (French, 2007, p. 83). Defined primarily by temperature and time, permafrost is associated with a range of physical properties and can occur within bedrock, unconsolidated sediments, and organic materials such as peat. Permafrost often contains water either as a liquid or as a solid (ground ice), and it is

important therefore to differentiate between its temperature and state. The terms ‘cryotic’ (≤ 0 °C) and ‘noncryotic’ (> 0 °C) relate solely to temperature, whereas the terms ‘frozen’ and ‘unfrozen’ refer to the state of any included water. In this respect, numerous factors, including pressure, soil particle size, and the presence of impurities, can depress the temperature at which ice starts to nucleate, and so the thermal boundaries between cryotic/noncryotic and frozen/unfrozen can differ by several degrees Celsius (Williams and Smith, 1989). Hence, permafrost is ‘perennially cryotic’ and may be frozen (e.g., ice-bonded) or unfrozen. In comprising a varied mixture of ice, water, and sediment, and being associated with genetic processes essentially identical to those associated with subaerial permafrost, subglacial permafrost can be physically and structurally indistinguishable from the debris-rich ice in the basal layers of glaciers and ice sheets (Hughes, 1973). Consequently, some confusion exists within the literature as to whether such mixtures should be considered part of the glacier (i.e., basal ice) or part of the glacier bed (i.e., frozen subglacial sediment) (Fitzsimons, 2006).

Most permafrost develops subaerially in response to climatic regimes where the mean annual air temperature remains below 0 °C. Glacier–permafrost interactions are therefore commonly associated with ice margins advancing into areas of pre-existing permafrost. However, ice-bonded permafrost can develop or persist subglacially if the temperature of the basal ice remains below the pressure melting point, that is, beneath cold-based glaciers. Conversely, beneath warm-based glaciers, where the basal ice remains at the pressure melting point, the heat flux associated with both active basal processes and the production of large volumes of meltwater is inimical to the long-term survival of ice-bonded permafrost, although unfrozen permafrost may persist.

While direct observations of the extent of subglacial permafrost are sparse, numerical and geomorphological reconstructions suggest that there are three principal situations in which it can occur:

- *Ice-marginal zones where cold basal temperatures are promoted by thin ice cover:* While steady-state models and field observations initially suggested that this zone is restricted to a few kilometers in width (e.g., Mooers, 1990; Moran et al., 1980), transient modeling indicates that subglacial permafrost may extend for tens to hundreds of kilometers during periods of ice advance (Cutler et al., 2000).
- *The interior of ice masses, where air temperatures are at a minimum:* Cold firn can be advected to the base of the ice mass, and flow-related strain heating is minimized by low ice-surface slopes (Dyke, 1993).
- *Areas of strong flow divergence:* The ice rapidly thins and strain heating is minimal (Dyke, 1993).

The spatial extent of cold-based ice and subglacial permafrost can change significantly during a glacial cycle, thereby

influencing rates of ice-sheet growth and decay. Ice temperature modeling of the late Pleistocene Laurentide Ice Sheet has suggested that the growth phase up to the Last Glacial Maximum (LGM) was associated with widespread frozen-bed conditions, with the cold-based area remaining at ~65% for 70 000 years (Marshall and Clark, 2002). Following the LGM, the area of warm-based ice increased exponentially in response to the increased insulation promoted by thicker ice and a combination of geothermal and strain heating. This led to increased flow velocities and the rapid decay of the ice sheet. Geomorphological studies have also indicated that cold-based conditions and renewed growth of subglacial permafrost can occur during deglaciation, due to reductions in ice thickness and basal shear stress (Dyke, 1993).

Basal Processes Beneath Cold-Based Ice

Traditional Views

Glacier–permafrost interactions are generally attributed to cold-based or polythermal glaciers in which basal temperatures remain below the pressure melting point. In this situation, glaciologists have traditionally assumed that basal processes are of little significance due to the limited supply of meltwater to the glacier bed, which is thought to be required to drive both basal sliding and subglacial sediment deformation. Cold-based ice resting on permafrost is therefore often conceptualized as ‘frozen to the bed,’ such that ice flow occurs only through internal creep (e.g., Boulton, 1972). This assumption is commonly used as a boundary condition in numerical ice-sheet models, which prescribe a velocity of zero if the basal temperature is calculated to be below the pressure melting point. This zero velocity at the ice bed was seemingly corroborated by empirical measurements beneath Meserve Glacier, a small cirque glacier in Antarctica with a mean basal temperature of -18.8°C , where a variety of techniques failed to record any movement across the ice–bed contact (Holdsworth and Bull, 1970). As basal processes are associated with erosion and sediment transfer, their absence is also thought to limit the erosivity of cold-based glaciers, although strong adhesion between the ice and the bed may promote plucking and removal of rafts of bedrock or frozen sediment (Boulton, 1972). Consequently, cold-based glaciers have typically been viewed as slow moving and geomorphologically impotent, and of limited research interest.

Evidence for Active Basal Processes Beneath Cold-Based Ice

The assumption that basal processes remain inactive beneath cold-based ice and therefore are always geomorphologically ineffective has been challenged (Waller, 2001). Central to this is the realization that liquid water can persist at temperatures well below the pressure melting point as nanometer-thick interfacial films at ice–bed or ice–particle interfaces, thereby facilitating both sliding and sediment deformation. Gilpin (1980) demonstrated the occurrence of regelation around a weighted wire at temperatures down to -35°C , providing a model that was subsequently used by Shreve (1984) to demonstrate the potential for non-zero sliding speeds at subfreezing temperatures. However, it was Echelmeyer and Zhongxiang’s

(1987) direct observation of basal motion beneath a predominantly cold-based glacier in China that forced glaciologists to reappraise their views on the dynamics of glaciers resting on permafrost. Using a tunnel excavated in the base of the Urumqi Glacier Number 1, they observed both sliding over bedrock and deformation of a layer of ‘ice-laden drift’ equivalent to 85% of the surface motion, in spite of recorded temperatures remaining below -1.75°C . Direct observations of the subglacial zone of the Suess Glacier in Antarctica (basal temperature of -17°C) suggest that ice lenses and lenses lacking pore ice can provide potential lines of weakness, permitting bed deformation and the entrainment of debris at very low temperatures (Fitzsimons, 2006). Additionally, repeat measurements at the Meserve Glacier have demonstrated small but measurable sliding rates of between 2 and 8 mm a $^{-1}$ at a temperature of -17°C (Cuffey et al., 1999).

Stratigraphic observations of formerly glaciated regions where permafrost has remained intact since its deformation by Pleistocene ice sheets provide a vital additional insight into the nature of glacier–permafrost interactions. Work in Western Siberia (Astakhov et al., 1996) and the Western Canadian Arctic (Murton et al., 2004) has demonstrated their extensive nature, with Astakhov et al. (1996) concluding that, “our inspection of frozen relicts of the Pleistocene glaciation in Siberia shows ubiquitous traces of this process over vast expanses, sediment sheets tens to hundreds of metres thick being involved in subglacial deformation” (p. 186). These studies highlight the crucial role played by a combination of temperature, ice content, and liquid water content. While coarse-grained sediments freeze at temperatures close to the pressure melting point, fine-grained sediments can retain significant quantities of liquid water at temperatures as low as -20°C (Williams and Smith, 1989). Consequently, ice-rich and clay-rich sediments remain deformable at temperatures below the pressure melting point. By providing zones of weakness, such layers can result in a migration of the zone of maximum shear and the mobilization of the entire overlying sequence (Figure 1). Consequently, the thickness of partially frozen subglacial deforming layers is thought to be substantially greater than that of entirely unfrozen deformation sequences (usually <1 m thick) (Waller et al., 2009) (see Section ‘Geological Evidence’).

Geomorphological Evidence

Proglacial and Ice-Marginal Landforms

Geomorphological investigations of the ice-marginal environments surrounding former Pleistocene ice masses suggest that glacier–permafrost interactions were particularly active within these areas. Cold-based ice interacted with pre-existing frozen sediments to generate distinctive landform assemblages comprising push moraines or ice-thrust complexes, hummocky or controlled moraines, and meltwater channels. These constitute a landform assemblage potentially indicative of glacier–permafrost interactions (Dyke and Evans, 2005; Etzelmüller and Hagen, 2005).

Push moraines

Geomorphologists have long considered the importance of permafrost in the formation of push moraines (Boulton

Figure 1 Deformations associated with the interaction of the Kara Ice Sheet with pre-existing and deep-seated permafrost composed of clay and sand in West Siberia as described by Astakhov et al. (1996, p. 186). Stages 1–3 relate to progressive thickening of the ice during an advance. Parallel arrows indicate reconstructed velocity profiles, '0' marks the original ice-bed interface, and 'DS' represents the dynamic sole of the glacier.

et al., 1999; Haeberli, 1979; Kälin, 1971; Kupsch, 1962). Permafrost is considered particularly influential in the development of large, multicrested push moraines (Bennett, 2001; Figure 2), although Haeberli (1979) suggested that its influence extends to the development of smaller features in high mountain regions. Permafrost is considered influential for two reasons: First, ice-bonded permafrost is often thought necessary to increase sediment cohesion and explain the preservation of primary bedding within unconsolidated sedimentary units that have been heavily deformed (e.g., Kupsch, 1962). In combination with the development of strong adhesion between the advancing ice and the pre-existing permafrost, the enhanced rigidity facilitates stress propagation into the foreland. Second, the development of very high pore-water pressures at the base of pre-existing permafrost due to the restriction of drainage from subglacial aquifers is thought to provide an ideal décollement along which displacement can occur (Mooers, 1990) and, in some cases, result in the entrainment of large bedrock rafts (Moran et al., 1980). Research within

modern-day environments has clarified the role of proglacial permafrost. For example, Boulton et al. (1999) concluded that the development of a 1.5-km-wide push moraine at Holmstrømbreen, Spitsbergen, required cementation of the foreland by ice-bonded permafrost and the development of an artesian head beneath this aquiclude of around 40 m.

Hummocky, controlled, and ribbed moraines

Glacier–permafrost interactions can also promote the formation of debris-rich ice margins and the subsequent development of hummocky or controlled moraines (Attig et al., 1989; Evans, 2009). Polythermal glaciers and ice sheets with cold-based margins terminating on permafrost are commonly associated with warm-based interiors where meltwater is generated. This water is driven to the cold-based margin by the gradient in ice overburden pressure where it refreezes, resulting in the net transport of water and the entrainment of thick sequences of basal ice (Weertman, 1961). Flow compression, folding, and thrusting can further thicken the sequence. The subsequent melt-out of this basal ice typically produces extensive areas of chaotic hummocky moraine or controlled moraines (where the melt-out of debris-rich structures imparts a linearity to the moraine) composed of melt-out tills, flow tills, and glaciofluvial sediments. The presence of hummocky terrain has consequently been used in Quaternary settings to delineate the extent of ice-marginal permafrost (e.g., Attig et al., 1989; Moran, et al., 1980). In regions where the permafrost has persisted since deglaciation, large volumes of ice buried within hummocky moraine can be preserved. Such 'retarded' deglaciation provides an extensive and potentially immensely valuable paleoglaciological archive the importance of which has yet to be explored (Grosvald et al., 1986).

Kleman and Hättestrand (1999) have suggested that a switch from frozen- to thawed-bed conditions can result in the extension, fracture, and boudinage of frozen till sheets to produce ribbed or Rogen moraines. They are therefore an additional landform considered indicative of changes in basal thermal regime.

Meltwater channels

The presence of permafrost clearly limits the generation of subglacial meltwater. But meltwater can be derived from other sources and locations. For example, in mapping the landscape impact of former ice caps in the Canadian High Arctic, Dyke and Evans (2005) highlighted the development of extensive networks of lateral meltwater channels eroded by supraglacial meltwater along cold-based ice margins. Such channels can provide a high-resolution record of ice recession. Attig et al. (1989) suggested that ice-marginal 'frozen-bed' zones can feature large tunnel channels associated with the episodic drainage of meltwater from warm-based areas located up ice.

Subglacial Landforms

Many glacial geomorphologists have assumed that cold-based glaciers resting on permafrost protect and preserve preglacial landforms. This view is commonly employed in

Figure 2 Proglacial moraine complex at the margin of the Leverett Glacier, western Greenland (67°03'28"N, 50°10'50"W), associated with ice advance into pre-existing permafrost.

geomorphological inverse models that relate the occurrence of preglacial features such as tors and patterned ground to cold-based conditions, in contrast to flow lineations such as drumlins generated beneath areas of warm-based ice (Dyke, 1993; Kleman and Borgström, 1996). As areas lacking clear evidence of landscape modification can also be interpreted as having been unglaciated (i.e., nunataks), this has led to significant variations in Quaternary ice-sheet and sea-level reconstructions, although cosmogenic isotope dating is helping to resolve these debates.

Even where processes at the ice-bed interface itself are inactive, glacial erosion and entrainment may still occur. Boulton (1972) suggested that englacial debris can come into contact with the bed if the flow lines intersect protuberances. Adhesion of the glacier sole to the bed can also result in quarrying or plucking of large lithified or unlithified erratics if the pressure melting point isotherm is at a shallow depth and the bed contains favorably orientated discontinuities.

Geomorphological mapping of glacier forelands in East Antarctica has revealed a range of distinctive landforms produced by cold-based glaciers that provide evidence of their ability to erode, transport, and deposit. While the basal temperatures beneath nearby glaciers were estimated at -24°C , Atkins et al. (2002) documented a range of features reflecting the plucking of clasts from the stoss side of bedrock outcrops, their dragging across the bed to create abrasional features such as striae, and their deposition as comminuted breccia, isolated boulders, or ice-cored cones. Working on the Meserve Glacier in Antarctica, Cuffey et al. (2000) measured sediment transfer rates of $10\text{--}30\text{ m}^3\text{ a}^{-1}$ associated with the entrainment and transport of eroded material within a basal ice layer. While the corresponding denudation rates of 9×10^{-7} and $3 \times 10^{-6}\text{ m a}^{-1}$ are very low compared to warm-based glaciers, they demonstrate the potential of cold-based glaciers to create significant landforms, given long time periods.

Geological Evidence

Cold-based ice can actively couple with and deform seasonally frozen ground or permafrost. Bennett et al. (2003), for example, described the occurrence of attenuated ice blocks and ice-filled shear planes in a frozen diamicton exposed following the winter surge of an Icelandic outlet glacier. The ice blocks

were attributed to the collapse of a rapidly advancing and heavily crevassed ice margin and entrainment into an initially unfrozen subglacial sediment. Subsequent attenuation to form augen-like structures highlighted a transition to subfreezing conditions during which deformation remained active (Figure 3(a)). While the short-lived nature of these conditions means they do not reflect glacier–permafrost conditions *sensu stricto*, they provide an insight into the style of deformation associated with deformation under subfreezing conditions.

Investigations of permafrost sedimentary sequences in Western Siberia (Astakhov et al., 1996) and the Western Canadian Arctic (Murton et al., 2004, 2005), which were deformed by the high-latitude margins of Kara and Laurentide Ice Sheets and have subsequently remained frozen, provide clear evidence for the widespread occurrence of Pleistocene glacier–permafrost interactions. They also highlight the related geological processes and products:

- The rheological complexity of permafrost sequences associated with variations in ice content and particle size. Astakhov et al. (1996) documented structures indicative of both ductile and brittle deformation. Sands are comparatively rigid, deforming via brittle failure (unless ice rich) to create boundinaged sand lenses or boudins. In contrast, both ice-rich and clay-rich sediments deform comparatively easily and in a ductile manner. Murton et al. (2004) described recumbent and S-shaped folds, sand lenses, and layers within glacially deformed permafrost, inferring the ductile deformation of warm, ice-rich materials (Figure 3(a)). Collectively, these structures reflect simple shear and extension consistent with submarginal rather than proglacial glacio-tectonic deformation. Significantly, the thickness of glacially deformed permafrost is substantial. Astakhov et al. (1996) reported thicknesses of tens to hundreds of meters (Figure 1), while Murton et al. (2004) reported thicknesses of at least 5–20 m (Figure 3(c)).
- Deformation was accompanied by erosion of permafrost. Murton et al. (2004) described blocks of ice up to 15 m long and 1.5 m high, some folded, dispersed throughout the glaciectonite (Figure 3(c)). Submarginal erosion of ice also explains the occurrence of an angular unconformity (décollement surface) along the top of the underlying massive ice. Preservation of these ‘ice clasts’ and the massive ice indicates that erosion occurred at subfreezing temperatures.

Figure 3 Geological evidence of glacier–permafrost interactions: (a) ice augen (~60 cm long, ice flow from left to right, highlighted by the arrow) situated within frozen diamict at the margin of Hagafellsjökull-Eystri, Iceland ($64^{\circ}31'19''$ N, $20^{\circ}9'29''$ W); (b) attenuated sand lenses and fold noses within silty clay (trowel for scale), North Head, Western Canadian Arctic ($69^{\circ}43'26''$ N, $134^{\circ}25'40''$ W); (c) frozen glaciectonite overlying massive ice (person for scale), Pullen Island, Western Canadian Arctic ($69^{\circ}46'27''$ N, $134^{\circ}24'26''$ W); and (d) streamlined sand intraclasts within laminated diamict (penknife for scale) at West Runton, North Norfolk, UK ($52^{\circ}56'36''$ N, $1^{\circ}13'41''$ E).

- Relict basal ice from the Laurentide and Kara Ice Sheets is also widely preserved in both glaciated regions. This is because permafrost there has existed continuously since before the last glaciation, with the result that deglaciation has been arrested, and will not be completed until the permafrost that preserves the glacial ice has degraded.
- The injection of pressurized water into proglacial permafrost occurred during the retreat of the Laurentide Ice Sheet (Morton, 2005). Superimposed on some glacially deformed permafrost are undeformed dykes and sills of intrusive ice and some undeformed massive segregated–intrusive ice which clearly postdates deformation.

Widespread permafrost development during Pleistocene glacial periods suggests that glacier–permafrost interactions are likely to have occurred around some mid-latitude margins of ice sheets during their initial advances. Subsequent permafrost degradation would, however, have destroyed or disrupted ice-hosted structures that provide incontrovertible evidence of the interactions within modern-day permafrost regions. Waller et al. (2011) have suggested that sand intraclasts

commonly found within till sequences may provide diagnostic sedimentological evidence for former glacier–permafrost interactions. Numerous authors have questioned the likely survival of these unconsolidated sand masses that frequently contain undisturbed primary bedding within otherwise heavily deformed sequences. Waller et al. (2011) argued that particle-size induced variations in the quantity of liquid water associated with ‘warm permafrost’ provide a simple explanation for the rheological heterogeneities between the comparatively rigid sand intraclasts and the surrounding, more easily deformed fine-grained tills observed within glaciectonic sequences at West Runton, North Norfolk, UK (Figure 3(d)). Their entrainment is also consistent with Boulton’s (1972) prediction that the subglacial quarrying and entrainment of unlithified rafts is a process most likely associated with cold-based ice. If correct, this will allow sedimentological evidence to be used in combination with geomorphological evidence (e.g., Kleman and Borgström, 1996) to reconstruct the basal thermal regimes of Quaternary ice sheets.

Permafrost aggradation during deglaciation may also be associated with distinctive sedimentological evidence. A progressive cooling of the subglacial permafrost could lead to a

switch from ductile to brittle deformation and the development of polyphase tectonic structures (Murton et al., 2004).

Conclusion

Although glaciers and permafrost have often been considered largely mutually exclusive, recent work has led to an increasing awareness of the important role played by active glacier–permafrost interactions, particularly in ice-marginal settings. Transient ice-sheet model outputs suggest that subglacial permafrost may extend for tens to hundreds of kilometers up-glacier of the margin during advances into areas of thick permafrost. In addition, field observations within both modern and Pleistocene glacial environments have falsified the assumption that basal processes are inactive beneath cold-based ice. In certain circumstances, the persistence of interfacial films of liquid water adsorbed to particles and bedrock surfaces at temperatures well below the pressure melting point can sustain non-zero sliding velocities and allow partially frozen sediments to deform. Where soft-bedded glaciers overlie ‘warm permafrost,’ these processes can dominate total surface motion. Even beneath very cold ice, this can lead to some erosion, entrainment, and sediment transport.

Glaciers overlying permafrost generate a variety of distinctive landforms and sediments. The presence of ice- and clay-rich layers within permafrost or, alternatively, the attainment of high pore-water pressures at the base of permafrost can provide potential décollement surfaces and result in the mobilization of bedrock rafts or sequences tens to hundreds of meters thick as the dynamic bed is displaced from the ice-bed interface into the permafrozen substrate. This can generate complexly deformed sequences or push moraines at the ice margin. Net basal adfreezing, thrusting, and folding can also lead to the creation of thick basal ice sequences beneath the cold-based margins of polythermal glaciers, which can subsequently melt out to produce large tracts of hummocky or controlled moraine. Alternatively, in permafrost regions, they can lead to the burial and preservation of large volumes of massive ice. Finally, the presence of transitions from cold- to warm-based ice can lead to the development of Rogen moraines.

Further research is required to determine the extent and rheology of subglacial permafrost. Identification of diagnostic sedimentological evidence for glacier–permafrost interactions in particular will complement geomorphological inverse models and help constrain their spatial extent beneath Quaternary ice sheets and by analogy, modern-day ice masses. Further work is also required to elucidate the conditions under which basal processes remain active at subfreezing temperatures and to constrain their varying contribution to glacier flow and geomorphic activity at different temperatures and in different substrates. This will both clarify the role of glacier–permafrost interactions and allow their inclusion into ice-sheet models.

Block/Rock Streams

P Wilson, University of Ulster, Coleraine, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

Block streams (or rock streams) result from the accumulation by mass wasting of coarse rock debris and extend a greater distance downslope than across slope. Thus, they are linear deposits with downslope alignment and occupy some hillslopes and valley axes in areas of past or present periglacial conditions (White, 1976, 1981). Most of the block streams described in the literature are relict features. Active block streams are those that continue to move downslope under the influence of the locally prevailing climate.

Block streams have often been confused with block fields, block slopes, talus, and rock glaciers, probably because these features can occur in close proximity and may grade into one another, making it difficult to isolate and delimit individual forms. In the Falkland Islands, South Atlantic, where (relict) block streams are known as stone runs, Clark (1972) recognized that they were components of a former cold-climate erosion–transport–deposition system that included (1) hilltops (debris source areas) characterized by block fields, altiplanation terraces, and residual tors; (2) hillsides (zones of debris transport) dominated by frost-riven crags, scree, block terraces, and stone runs; and (3) valleys (zones of debris accumulation) occupied by stone runs and sheets of head. It is likely that block streams in many other regions are also part of a local continuum of blocky materials, and this is probably the reason for some of the terminological confusion encountered in the literature. Further confusion may have arisen because (active) block streams and stone runs have been considered to be distinctly different features (Harris, 1994). Adopting the basic morphotopographical definition given previously enables a range of block-stream forms of various dimensions, gradients, and composition to be accommodated and allows both relict and active features to be included.

Geographical Distribution of Block Streams

Block streams have been recorded in many areas of the world and are generally found at low to high altitudes in the mid- to high latitudes or at high altitudes in the low latitudes. These are the regions that either currently experience periglacial climatic conditions or did so at various times during the Pleistocene. However, the total area occupied by block streams is not known, although it is undoubtedly very small. In the Northern Hemisphere, block streams have been recorded in parts of the United States and Canada (Harris and Pedersen, 1998; Nelson et al., 2007; Potter and Moss, 1968; Smith, 1949, 1953), China (Harris et al., 1998), Russia (where they are called kurums; Perov, 1969; Romanovskij and Tyurin, 1986), Italy (Firpo et al., 2006), and England (Bennett et al., 1996; Clark, 1994). In the Southern Hemisphere, block streams have been reported from Australia (Caine, 1983; Caine and Jennings, 1968), South Africa (Boelhouwers, 1999; Boelhouwers and Sumner, 2003), and the Falkland Islands (Andersson, 1906, 1907; Clark, 1972).

Characteristics of Block Streams

Plan Form

Block streams can assume a range of plan forms (Figure 1). A single-thread form (straight or sinuous) may occur in part or along the entire block-stream length; such patterns are usually confined to valley axes. Some axial block streams with numerous tributary feeder block streams have a dendritic plan. On more open slopes, braided or anastomosing plans can develop, and with increasing distance downslope, this pattern may grade into a single-thread form. In the Falkland Islands, many block streams consist of parallel block stripes. These can diverge from and/or converge into more extensive hillside or axial block spreads.

Dimensions

There is great variation in the reported dimensions of block streams. They range from widths of up to a few tens of meters and lengths of up to a few hundred meters to widths of several hundred meters and lengths of up to 5 km (Barrows et al., 2004; Clark, 1972; Harris et al., 1998; White, 1976). Quoted dimensions for some relict block streams are likely to be minima. Several reports refer to coarse debris being overlain by peat and vegetation along block-stream margins, indicating a continuation of debris beyond the apparent limits (Andersson, 1906; Caine and Jennings, 1968; Smith, 1949).

Morphology

A surface consisting of openwork rock debris is common to all block streams, but there is usually considerable morphological diversity both across individual block streams and between them. Some block-stream surfaces are diversified by random or aligned pits and elongated depressions, whereas others have longitudinal furrows extending for considerable distances along their central tracts. Such features can be 2 or 3 m in depth. Along the longitudinal axis of many block streams, boulder steps, arcuate ridges, and lobes occur. These rise between 0.5 and 9 m above the areas immediately downslope, and it is not always clear whether they are controlled by underlying rock scarps or represent overriding masses (flow structures) of coarse debris (Barrows et al., 2004; Boelhouwers, 1999; Clark, 1994; Potter and Moss, 1968).

Although block-stream longitudinal gradients are generally $<15^\circ$, with values as low as 1° or 2° being reported (Andersson, 1907; Caine, 1983; Clark, 1972; Smith, 1953), gradients of approximately $30\text{--}35^\circ$ have also been recorded (Barrows et al., 2004; Harris and Pedersen, 1998; Harris et al., 1998; Perov, 1969). On relict block streams, gradients in excess of 15° are usually, but not exclusively, associated with the distal slopes of steps, ridges, and lobes and also with the terminal zone (Boelhouwers, 1999; Caine, 1983; Potter and Moss, 1968).

Figure 1 Situations and plan forms of block streams. (a) Single-thread valley-axis block stream near Sani Pass, Lesotho. Reproduced from Boelhouwers JC, Holness S, Meiklejohn I, and Sumner P (2002) Observations on a block stream in the vicinity of Sani Pass, Lesotho Highlands, Southern Africa. *Permafrost and Periglacial Processes* 13: 251–257. © John Wiley & Sons. (b) Valley-axis block stream with tributary feeder block streams (dendritic plan form), Falkland Islands. (c) Block stream with braided or anastomosing plan form, Falkland Islands. (d) Parallel block stripes, Falkland Islands.

Some block streams are downslope extensions to talus and/or block fields/block slopes; these block streams are usually considerably steeper in their upper reaches than in their lower reaches. Other block streams originate from rock scarps or tor-like outcrops, whereas some are sourced from the upper parts of convex ridges that lack upstanding outcrops (Figure 2; Boelhouwers, 1999; Clapperton, 1975; Potter and Moss, 1968; Romanovskij and Tyurin, 1986), deposits of till (Harris et al., 1998), debris terraces (Clark, 1972), and low-gradient solifluction slopes (Barrows et al., 2004).

Block-stream margins may display either a smooth or an irregular form in different parts and can be sharp or diffuse, the latter usually being associated with the encroachment of peat and vegetation from adjacent ground. Terminal areas of block streams have often been reported as being lobate in plan and convex in profile, but Smith (1968) described a block-stream toe in the Beartooth Mountains of Wyoming and Montana as having a V-shaped reentrant descending 10 m to a lower boulder zone. A similar stepped reentrant has been observed in the front of a Falkland Islands block stream.

Structure and Composition

Some relict block streams have attained thicknesses of 9 or 10 m in part (Boelhouwers, 1999; Potter and Moss, 1968; White, 1981), although average thicknesses tend to be in the

range of 1–3 m. Romanovskij and Tyurin (1986) cited examples of active kurums in Arctic regions of Russia as being 0.3 or 0.4 m thick, and Harris et al. (1998) described an active block stream in China with a thickness of 0.15 m.

Block streams, and other coarse blocky accumulations, are usually found on well-jointed igneous and metamorphic rocks, presumably because these lithologies are susceptible to macrogelivation, thermal stress fracturing, and/or deep chemical weathering along existing joints. These processes, acting on well-jointed rocks, usually produce numerous large blocks. The English language block-stream literature is dominated by examples developed on quartzite, basalt, and dolerite.

Several records exist of relict block-stream stratigraphy, as observed in road cuts or natural exposures. These generally indicate a marked decrease in block size with increasing depth (inverse grading) and a lack of interstitial fine material in at least the uppermost part of the debris (Figure 3(a); Boelhouwers, 1999; Clapperton, 1975; Clark, 1972, 1994; Potter and Moss, 1968; Smith, 1953). The most detailed descriptions of block-stream structure are those from southeastern Australia by Caine and Jennings (1968) and Caine (1983). Three stratigraphic units have been recognized. The uppermost is a 0.5–3-m-thick matrix-free layer of openwork blocks with minor quantities of angular gravel. Below this occurs a block layer 0.2–0.6 m thick with void space occupied by organic-rich fines and capped by a 0.01–0.03-m-thick layer of gravel derived

Figure 2 Examples of block-stream source areas, in the Falkland Islands. (a) Block stream originating from a 2-m-high rock scarp. (b) Block stream originating from near the crest of a convex ridge without upstanding outcrops.

from weathering of the overlying blocks. The upper surface of this layer is usually at the level of the local water table. The basal layer consists of blocks with intervening void space filled by yellow brown/dark brown silty sand and is up to 0.5 m thick. Beneath the block streams, deeply weathered bedrock is present in which some original structures are preserved.

Sections across block stripes in the Falkland Islands show that some display inverse grading and occupy depressions in the underlying fine-grained material. Beneath the adjacent vegetated stripes, fine-grained material containing relatively few boulders is found (**Figure 3(b)**). Although the stratigraphy of active block streams is little known beyond the statement given by **Harris et al. (1998)** that a sandy loam underlies a 0.15-m-thick layer of blocks, it indicates that materials of considerably finer grain size underlie even shallow block accumulations.

Measures of the size and shape of clasts contained within block streams reveal that marked variations exist. Surface clasts between 0.2 m and several meters in length have been reported (**Bennett et al., 1996; Clark, 1994; Perov, 1969**). Blocks 6–8 m in length were recorded by **Andersson (1907)**, **Smith (1949, 1953)**, and **Potter and Moss (1968)**. A 9-m-long block occurs in a Falkland Islands stone run (**Figure 4**). **Aldiss and Edwards (1999)** noted local variations in block size. Statements to the effect that average block size decreases with increasing depth (inverse grading) in block streams have rarely been supported by detailed measurements, although photographic evidence

Figure 3 Vertical exposures beneath block streams. (a) Inverse grading and an absence of fine-grained material in a Falkland Islands stone run. Survey pole (left center) is 1 m in length. (b) Block stripes in the Falkland Islands. The central stripe has inverse grading and occupies a shallow depression. Note the relative lack of blocks in fine-grained material beneath adjacent vegetated ground and block stripes. Survey pole (center) is 1 m in length.

Figure 4 A 9-m-long block in a Falkland Islands stone run. Survey pole (center) is 1 m in length, and arrows indicate where the *a*-axis of the block is partly concealed by smaller blocks.

has been presented (**Boelhouwers, 1999; Clapperton, 1975**). Few studies have considered the downslope variation in size of surface blocks, and among those that have there is no general consensus. **Caine and Jennings (1968)** noted a reduction in

block size downstream, whereas [Potter and Moss \(1968\)](#) and [Boelhouwers et al. \(2002\)](#) found little variation in block size along block-stream axes.

Clast shapes have frequently been referred to but rarely quantified. Shape terminology includes tabular, platy, elongate, equant, slab, and diamond-shaped, angular, subangular, subrounded, and edge rounded, without clear definitions. Therefore, it is difficult to compare block streams in different locations. Some of the variation in clast size and shape is probably related to characteristics inherited from the parent rock, particularly the spacing of joints, and some may be a function of weathering and erosion during and since block accumulation.

Assessments of block-stream clast fabrics have yielded a wide range of results. A preferred downslope orientation of surface clasts is mentioned in several publications, but supporting fabric diagrams have not always been presented. Where such diagrams do occur, they show (1) blocks to be well oriented with either upslope or downslope dips ([Harris et al., 1998](#); [Potter and Moss, 1968](#)), (2) blocks to have a distinct cross-slope orientation or a random pattern in the vicinity of block-stream confluence sites ([Boelhouwers et al.,](#)

[2002](#); [Harris et al., 1998](#)), (3) blocks to have a primary downslope orientation and a secondary cross-slope orientation ([Boelhouwers et al., 2002](#); [Caine, 1983](#)), and (4) blocks with no preferred orientation ([Bennett et al., 1996](#)). In addition, blocks with a transverse orientation and upslope dip have been recorded by [Boelhouwers \(1999\)](#) at the front of a block stream, and a tendency for clasts to be arranged on edge has been noted in certain areas of some block streams ([Aldiss and Edwards, 1999](#); [Clapperton, 1975](#); [Clark, 1994](#)). Two-dimensional fabric diagrams presented by [Boelhouwers et al. \(2002\)](#) for a South African block stream are an indication of the variations that can occur in clast orientations ([Figure 5](#)). These variations are probably, in part, a reflection of the distance and mode of downslope transport.

Thermal Regime of Active Block Streams

Pronounced differences exist between the thermal regime of coarse blocky materials and adjacent mineral soils. Mean annual ground temperatures 4–7 °C cooler than in adjacent

Figure 5 Two-dimensional fabric diagrams for surface blocks on a block stream in Lesotho. Reproduced from [Boelhouwers JC, Holness S, Meiklejohn I, and Sumner P \(2002\) Observations on a block stream in the vicinity of Sani Pass, Lesotho Highlands, Southern Africa. *Permafrost and Periglacial Processes* 13: 251–257. © John Wiley & Sons.](#)

mineral soils were recorded by [Harris and Pedersen \(1998\)](#) during a 2-year period in a block stream in southwestern Alberta. The cause of the disparity was attributed to continuous air exchange between the atmosphere and the block-stream void space, assisted by strong winds that favored evaporative cooling. This mechanism was thought to explain the occurrence of permafrost and ice masses in blocky deposits below the margin of regional continuous permafrost.

In central Asia, [Gorbunov et al. \(2004\)](#) found that mean annual air temperatures (MAATs) inside blocky deposits were 2.5–4 °C cooler than the air temperature above the surface. It was concluded that in such situations, permafrost could develop under positive MAATs of 4 °C. Similarly, [Guodong et al. \(2007\)](#) have demonstrated that in periglacial areas, coarse rock layers can behave like a ‘thermal semiconductor’ and lower the temperature of the underlying ground. Cooling is attributed to the ‘chimney effect’ (a natural form of convection driven by density buoyancy) and wind-forced convection. As well as having significant engineering applications, these findings have implications for understanding the processes involved in the creation of relict block streams.

Processes of Block-Stream Formation

Block streams are a consequence of several processes acting in combination or succession. [Harris et al. \(1998\)](#) found that blocks on an active block stream were derived by frost shattering of rock outcrops and by frost heaving from till. The downslope movement of active block streams has been attributed to the creeping and sliding of blocks in association with void-space ice. During the winter, ice forms in block streams and accompanying frost heave and thaw settlement cause some downslope movement of blocks. Other movement occurs when near-surface ice and snow begin to melt; friction between blocks is reduced and lubrication by water enables them to slide across the underlying ice-covered/cemented blocks ([Harris et al., 1998](#); [Romanovskij and Tyurin, 1986](#)).

The processes that contributed to the development of relict block streams have generated considerable discussion. A four-stage evolution has been envisaged, comprising (1) the mechanism(s) of block production, (2) downslope movement by mass wasting, (3) frost heaving and vertical sorting of blocks during transport, and (4) immobilization of the blocks as a consequence of the removal of interstitial fine-grained material. Elements of this model were proposed by [Andersson \(1906, 1907\)](#) based on his observations of block streams in Bear Island and the Falkland Islands, and from which he introduced the term solifluction to explain the downslope movement of blocks.

It has frequently been inferred that blocky debris results from the frost shattering (macrogelivation) of rock outcrops. This is because many blocks are very angular and, in some areas, can be traced upslope to degraded outcrops around which openwork accumulations of the most recently released blocks occur ([Boelhouwers, 1999](#); [Clark, 1972](#)). The absence of evidence for deep chemical weathering at such sites has served to reinforce the view that block production was a function of macrogelivation. However, very angular blocks occur in regions that have never experienced periglacial climates; in these situations, thermal stress

fracturing may account for the angularity ([Boelhouwers, 2004](#)). Therefore, block angularity cannot be taken as a diagnostic characteristic of macrogelivation. Rounded blocks have also been observed in block streams, and their origin as corestones, exhumed from deep chemically weathered mantles, has been proposed by [Caine and Jennings \(1968\)](#), [Caine \(1983\)](#), and [Boelhouwers et al. \(2002\)](#). Block fields on some Norwegian mountain plateaus consist of rounded blocks, and evidence for chemical weathering at these sites is given by [Rea et al. \(1996\)](#). Thus, block production may result from at least three different processes and, in certain areas, it is possible that each has contributed material to block streams.

Following [Andersson \(1906, 1907\)](#), some researchers have attributed the downslope movement of relict block streams either to solifluction or to the less specific process of mass wasting ([Aldiss and Edwards, 1999](#); [Boelhouwers, 1999](#); [Boelhouwers et al., 2002](#); [Caine, 1983](#); [Caine and Jennings, 1968](#); [Clapperton, 1975](#); [Potter and Moss, 1968](#); [Smith, 1949, 1953](#)). At most locations, it has been considered that the blocks moved in association with a matrix of fine-grained sediment. Indeed, [Aldiss and Edwards \(1999\)](#) considered it “mechanically unfeasible that stone runs could have moved without any matrix to separate the blocks.” However, at the head of some block streams, there are block piles adjacent to their source outcrops, and neither blocks nor outcrops show evidence for fine material ever having been present ([Boelhouwers, 1999](#); [Caine and Jennings, 1968](#); [Clark, 1972, 1994](#)). In these cases, frost wedging and heaving may have caused block movement away from outcrops, especially on very gentle slopes.

[Caine \(1983\)](#) reviewed two mechanisms of movement for block streams in Tasmania: a frictional mechanism and a viscous flow mechanism. These were not viewed as being mutually exclusive; both could have been involved in varying degrees. For a frictional model to apply, finer sediments and/or ice must have been present within the block-stream void space in order to facilitate high artesian pressures and shearing. Deep seasonal freezing and impervious weathered clays beneath block streams were thought to favor this mechanism, and permafrost was considered to be unnecessary. A viscous flow model based on frost heave and creep was thought capable of inducing some downslope block transport, whereas alternative viscous models were not likely to account for block movement. In conclusion, [Caine \(1983\)](#) considered that most of the movement resulted from sliding failure in remolded clays beneath the block streams when seasonal freezing occurred and high pore water pressures developed during thawing. Frost creep was regarded as a secondary process but one that could account for some block-stream fabrics.

The inverse grading evident in many block streams is generally attributed to block sorting as a consequence of frost heave during downslope transport ([Aldiss and Edwards, 1999](#); [Boelhouwers, 1999](#); [Potter and Moss, 1968](#)). Given the size of many surface blocks, it has been argued that heaving and sorting are likely to have been of greatest efficacy where block streams possessed a frost-susceptible matrix of fine sediment.

The absence of a fine-grained matrix from the upper thicknesses of relict block streams has been attributed to its removal following the cessation of downslope movement. Because running water can be heard and/or seen at the base of many block streams, it has been assumed that surface streams gradually

worked their way down through the blocks and removed the matrix. This has been referred to as the washing or flushing out of fines (Andersson, 1906, 1907; Boelhouwers, 1999; Boelhouwers et al., 2002; Caine, 1983; Caine and Jennings, 1968; Clapperton, 1975; Clark, 1994; Potter and Moss, 1968; Smith, 1949, 1953). Accumulations of fine-grained alluvium downstream of block fields were reported by Caine (1983) and Clark (1994), lending support to the notion of fluvial reworking.

Smith (1968) challenged the view that surface streams working downward had removed matrix materials. He proposed that piping (subsurface flow) was capable of removing material from situations and depths that could not be easily accounted for by surface flow, but this was recognized to be a speculative hypothesis requiring further testing.

In contrast, Aldiss and Edwards (1999) favored a process of matrix replacement by ice during freezing and flushing out of matrix by water during thaw. Because blocks have a greater thermal conductivity and a lower heat capacity compared to those of the matrix, it was argued that a coating of ice would develop around the blocks as the freezing front advanced into the block stream. Thus formed, the ice was thought to push the matrix particles away from the blocks, effectively separating the coarse and fine components. During times of thaw, some fine-grained material was likely to be flushed away by water and smaller blocks would be transported by water or gravity to a greater depth in the block stream, explaining the inverse grading that has frequently been reported. This mechanism, if valid, would have operated during downslope movement rather than following cessation of movement. Ultimately, an ice-bound block stream would develop and continue to move downslope until such time as the climate ameliorated.

The fact that block streams often possess strongly developed fabrics has been taken as evidence for downslope movement and fabric development prior to the removal of matrix (Boelhouwers and Sumner, 2003). However, it has not been explained satisfactorily how the fabric was retained when the removal of matrix seems likely to have resulted in some rearrangement of blocks (Potter and Moss, 1968). Strongly developed fabrics in an active block stream, consisting of blocks without interstitial material but with a sandy loam beneath, have been reported by Harris et al. (1998). Therefore, not all block streams require a fine-grained matrix in order for such fabrics to form. It appears that the development of fabrics in both active and relict block streams is an aspect that has not been fully elucidated.

From examination of some of the block streams of the Falkland Islands, André et al. (2008) proposed an alternative to the periglacial model of formation (Figure 6). They argued, from micromorphological, scanning electron microscopy (SEM), X-ray diffraction (XRD), and grain-size analyses, that the block streams are complex polygenetic landforms that have evolved through a six-stage development sequence. First, they suggested that the fine-grained material observed beneath the block streams was a product of intense and/or prolonged subtropical chemical weathering because the material had characteristics similar to those recorded in quartzite-derived tropical soils in Africa and South America. A Miocene age (23–5 Ma) for the weathering and regolith production was envisaged. Second, in the late Miocene–Early Quaternary (10–2 Ma), solifluction and debris sliding led to stripping of the upper part of the regolith from hillcrests and slopes,

resulting in accumulation of the material on the valley floors. Third, a phase of soil development then occurred, possibly associated with the temperate conditions of an early Quaternary interglacial stage. In the fourth stage, stripping of the remainder of the hillside regolith occurred. This material, essentially the middle and lower parts of the chemically weathered profile, consisted in down-profile sequence of cobbles embedded in fine-grained material and then larger blocks of quartzite; the latter now form the upper part of the block streams. André et al. (2008) were uncertain as to whether this phase of regolith stripping had occurred as a result of gelifluction under periglacial conditions or by other (nonperiglacial) mass-movement processes. Nevertheless, the removal (washing out) of the fine material was believed to have been either concurrent with or subsequent to debris emplacement in Quaternary cold episodes (fifth stage of the development sequence), and periglacial processes (frost heave and frost sorting) were implicated to account for some rearrangement of block-stream boulders in the final (sixth) stage. In essence, André et al. (2008) consider Falkland block streams to have strong affinities to inverted weathering profiles, with periglacial processes having played a relatively minor role at a late stage in their evolution.

The competing models of block-stream formation find similarities in the alternative models proposed to account for relict autochthonous block-field development. However, Ballantyne (2010) argued that evidence supporting both a pre-Quaternary chemical weathering hypothesis and a Quaternary periglacial (mechanical) hypothesis for block fields can be accommodated within a single evolutionary framework. Although plateau block fields were the focus of this inclusive model, the surface lowering envisaged by stripping of chemically weathered regolith cover and downslope transport by mass movement, followed by frost wedging of bedrock and downslope movement of blocks by frost creep and/or gelifluction may, in some circumstances, explain the occurrence of hillside and valley floor block streams. As with the hypothesis advanced by André et al. (2008), a variety of processes operating over a long period would therefore account for block-stream formation.

Rates of Movement of Active Block Streams

Harris et al. (1998) provided the most detailed results concerning rates of block movement on an active block stream. Seven lines painted across slope on a block stream 4800 m above sea level on a southwest-facing slope of 31° in Qinghai Province, China, were monitored for up to 5 years. MAAT of the site was estimated to be −6 °C and mean annual precipitation (MAP) 320 mm. Block movement was found to vary both across and along the block stream, with movement being greatest in the center and least near the source and the toe. Movement was only noted for surface blocks; in the subsurface, abundant plant stems were taken to indicate block stability. The maximum amount of movement of an individual block during a 12-month period was 2.1 m, but the maximum mean rate of movement along any line was considerably less at up to 0.6 m per year. Marked variations in mean rates of movement were recorded for most of the lines as well as between individual lines. A seasonal pattern to block movement was reported,

with most occurring between October and May when the ground was frozen but lacking a continuous snow cover. Some movement also occurred in June and July, probably in association with snow and freezing temperatures, but movement was minimal in August and September. Downslope movement resulted in block rotation, and small lobate clusters of moved blocks were observed close to the toe.

Climatic and Paleoclimatic Significance of Block Streams

Harris (1994) assessed the relationship of active block streams in China, Siberia, and North America to key climatic parameters. It was shown that they are associated with cold, dry climates (MAAT range, -6°C to -20°C ; MAP range, 50–500 mm) and occupy a discrete climatic zone that has limited overlap with zones characterized by active rock glaciers and active gelifluction landforms (Figure 7). However, the climatic conditions that currently favor active block streams are not necessarily the same as those under which relict block streams developed. Furthermore, it was argued that these zones display variations with respect to latitude, altitude, and aspect, with block streams being associated with higher latitudes and altitudes and with southwest and south slope aspects.

Attempts have been made to draw paleoclimatic inferences from relict block streams because they are thought to have undergone downslope movement associated with periglacial climatic conditions. Boelhouwers (1999) estimated that a MAAT of approximately 0°C was necessary for block-stream development in the Hex River Mountains, South Africa, implying a reduction of 7 or 8°C from present-day MAAT. Permafrost was not considered a prerequisite for block-stream mobilization; rather, deep seasonal frost penetration to 2-m depth was favored. In turn, this implies the lack of a sufficiently thick insulating snow cover during the autumn/winter freezing period. Again, however, the parameters that governed block-

stream development in one location are unlikely to have been identical to those that operated elsewhere. If more than one mechanism of downslope movement can account for block streams, then it may be the case that these mechanisms are controlled to a degree by the local climatic regime.

Age of Relict Block Streams

Many relict block streams occur in areas that lay adjacent to but beyond the margins of the (global) Last Glacial Maximum (LGM; 23 ± 4 ka). It has been inferred that these areas were characterized by severely cold periglacial climates at that time, and that block-stream formation represents one response of the landscape to those conditions (Boelhouwers, 1999; Boelhouwers et al., 2002; Clapperton, 1975; Clark, 1972, 1994; Potter and Moss, 1968).

A maximum age for block-stream formation in the Snowy Mountains, southeastern Australia, was provided by a ^{14}C age of $35.2 \pm 1.6 / -2.15$ ka obtained from *Nothofagus* wood from beneath a block stream (Caine and Jennings, 1968). Block-stream formation was attributed to a subsequent cold stage, coeval with the LGM. Caine (1983) reported ^{14}C dates of 3.08–4.7 ka from the base of soil and peat developed on block fields in Tasmania. These were taken to indicate that the block fields (and by inference the block streams) had been stable since at least the mid-Holocene. Using weathering rind thickness measurements of block-field clasts, Caine (1983) calculated that the block fields had probably been stable for approximately the past 13 ka.

Cosmogenic isotope (^{36}Cl) surface exposure dating of block streams and block slopes in southeastern Australia has shown a clustering of dates within the period of the LGM (Barrows et al., 2004). A weighted mean age of 21.9 ± 0.5 ka was obtained and is broadly equivalent to the timing of the maximum ice advance during the LGM as determined from cosmogenic dates from moraines in the region. These dates support earlier age estimates for relict block streams based on morphostratigraphy, ^{14}C assays, and weathering rind data. However, two boulders returned ages of 157 and 498 ka respectively, indicating that not necessarily all block-stream boulders were produced during the LGM.

Both optically stimulated luminescence (OSL) dating and cosmogenic isotope (^{10}Be and ^{26}Al) surface exposure dating have been applied to the block streams of the Falkland Islands. Hansom et al. (2008) collected samples for OSL dating from fine-grained materials from beneath and close to the downslope margins of block streams in order to constrain the emplacement age of the fine sediments and to provide maximum ages for deposition of the overlying blocks. Age estimates ranging from >54 to 16 ka were obtained and suggest that some block streams were probably active throughout the LGM and remained so until 16 ka or later.

The Falkland Islands block-stream dating undertaken by Wilson et al. (2008) involved sixteen ^{10}Be and ^{26}Al exposure ages and the results stand in marked contrast to the OSL dates reported by Hansom et al. (2008). Samples for dating were taken from one of the largest block streams (Prince's Street: ~ 4 km long and up to 400 m wide) and the smaller Estancia Brook block stream (~ 2.5 km long, 250 m wide), and were drawn

Figure 7 Relationship between climatic parameters (mean annual air temperature and mean annual precipitation) and distribution of gelifluction landforms, active rock glaciers, and active block streams in alpine landscapes. Reproduced from Harris SA (1994) Climatic zonality of periglacial landforms in mountain areas. *Arctic* 47: 184–192. © Arctic Institute of North America.

from different components of block-stream terrain: (1) valley-axis block accumulations, (2) narrow hillslope block streams that converge downslope with the valley-axis blocks and represent relict flow lines of block transport, and (3) hillcrest outcrops from which the blocks derived.

The range of ages obtained (731–42 ka) indicate that the samples cover a long period, at least 690 ka, and most have isotopic concentrations consistent with a simple exposure history. Ages of valley-axis blocks from Prince's Street are generally older than valley-axis blocks from Estancia Brook, and valley-axis blocks are generally older than samples derived from hillslope block streams. Two samples from hillcrest outcrops have isotopic concentrations indicative of a complex exposure history, most likely due to periods of burial and/or shielding. Overall, the ages demonstrate that the block streams date from more than one cold stage and can be considered as composite features that most likely formed over several cold stages. The block streams are long-lived landforms, as suggested by Aldiss and Edwards (1999). But just how close the earliest age obtained is to the start of block-stream activity is not known. In marked contrast to the OSL ages reported by Hansom et al. (2008), and some of the cosmogenic isotope ages for Australian block streams (Barrows et al., 2004), the ^{10}Be and ^{26}Al data of Wilson et al. (2008) provide no evidence for block-stream activity during the LGM.

The ages reported by these studies constitute a major advance in establishing a time scale for block-stream development, and may stimulate further and focused investigations on these enigmatic landscape features.

Blockfields (Felsenmeer)

B R Rea, University of Aberdeen, Aberdeen, UK

Introduction

Blockfields are found on plateaux, summits, and ridges and have also been described as blockmeer, felsenmeer, boulder fields, stone fields, and mountain-top detritus. There has long been an interest in these landforms, and interpretations have varied over time as views on the erosional efficacy of Pleistocene glaciers and ice sheets and understanding of geomorphic processes have changed (Goddard, 1989). Blockfields are to be found predominantly in high to mid-latitudes (Arctic Canada, Greenland, Fennoscandia, Iceland, Svalbard, UK, and USA) and are the focus of discussion in this article, though they are present at lower latitudes, for example, the Lesotho Highlands and Namibia (Boelhouwers, 2004) and Tasmania (Caine, 1983). They are characterized, as their name suggests, by a block-covered surface, which may extend to rockhead, or overlie a clast- or matrix-supported profile. The matrix may comprise sand-, silt-, and clay-size fractions.

The main subject of this article is autochthonous blockfields (formed *in situ* and confined to tectonically stable environments; Goddard, 1989), though para-autochthonous blockfields may be of relevance but only if the material is sourced locally and from weathering products produced contemporaneously, for example, up-slope (Nesje, 1989; Nesje et al., 1988). As material transport distance increases, the transport mechanism itself defines the character of the landform, with boulder-banked solifluction lobes, or larger boulder/block streams, making them irrelevant to this article. True allochthonous blockfields, derived for example from an old till cover (Roaldset et al., 1982), are not considered here.

The contentious issues regarding blockfields relate to their age and origin. For blockfields in mid- to high latitudes, both issues are interlinked: that is, the age can to some degree dictate the origin, and vice versa (Ballantyne, 1998; Goddard, 1989; Nesje, 1989; Rea et al., 1996a,b; Roaldset et al., 1982). Age ranges of <10 ka to >2 Ma, for different blockfields, have been postulated in the literature, suggesting a chemical weathering origin, a frost weathering origin, or some combination of both. This range of ages and thus weathering origins may have significant implications for the dynamics and geometry of Pleistocene ice sheets. For example, a pre-Pleistocene age (>1.8 Ma) indicates nonglaciation or glaciation beneath ice that was cold-based and nonerosive or experienced minimal erosion. To add further complexity, blockfield-mantled surfaces are often found in juxtaposition with deeply incised glacial valleys. For these reasons, the identification and interpretation of the age and origin of blockfields is of particular interest, especially in middle to high latitudes, within the regions affected by Pleistocene ice sheets. Their study may provide details on paleoclimates, glacier/ice sheet geometries and dynamics, and landscape evolution over short or longer time periods. In the following sections, we present the key characteristics, age and origin, implications for ice dynamics and landscape evolution, paleoclimate, and future prospects for studies on blockfields.

Blockfield Characteristics

Surface

The formation/preservation of blockfields is obviously controlled at a first order by slope angles. As the slope angle increases, the downslope shear stress on a particle increases, initiating ever greater rates of movement, thus preventing blockfield formation. Dahl (1966) reports an upper limit of 25° for the presence of blockfield slopes; beyond this, talus slopes form, and Rea et al. (1996a) report blockfield cover on slopes of <10° on plateaux in north Norway. Blockfields may be found as extensive spreads (Figure 1(a)) often in association with tors (Dyke, 1993; Ives, 1958; Kleman and Borgstrom, 1990; Rea et al., 1996a; Sugden and Watts, 1977; Figure 1(b)) or small areas confined to summits and ridges (Figure 1(c)). Generally, the surface cover is either an openwork of blocks ranging from cobble through to boulder sizes (Figure 2(a)), or a similar blocky surface set in a matrix of fines (Figure 2(b)). An openwork blocky surface will tend to display crude sorting patterns with perhaps some imbricate boulders. Much better developed sorting is found on surfaces where there are more fines (Figure 3). The removal of fine-grained matrix sediments is more effective on steeper slopes, making openwork blockfields more prevalent as the slope angle increases (Rea et al., 1996a,b). Large boulder sizes favor the formation of an openwork blockfield. Lower slope angles will tend to retain fines and may accumulate them from up-slope. The exposed surfaces of blockfield boulders and associated tors tend to be heavily weathered, often showing a significant degree of breakdown through granular disintegration, and forms such as weathering pits may be common (Ballantyne, 1998; Dahl, 1966).

Profile

The depth of blockfields is obviously controlled by a number of variables, including age, slope angle, lithology, and weathering versus erosion rate. An average seems to be on the order of 1 m, with excavated depths exceeding 1.5 m in places without reaching rockhead (Ballantyne, 1998; Dahl, 1966; Rea et al., 1996a,b). Fjellanger et al. (2006) and Fjellanger and Sørbel (2007) observed depths >2 m and inferred depths of >3 m for the Varanger Peninsula, north Norway. The nature of the deposits also often precludes excavation to rockhead, making accurate depths difficult to determine, although admirable digging efforts have demonstrated that this can be achieved (Goodfellow et al., 2008).

Ballantyne (1998) reported three primary types of blockfield profile:

- Type 1 is clast-supported, and has an openwork blocky surface with fines forming a matrix at some depth below the surface (Figures 4(a), 1(b) foreground and Figure 2(a)).
- Type 2 is matrix-supported, and the surface has blocks set in a cohesionless sandy matrix that continues down through the profile (Figure 4(b)).

- Type 3 is matrix-supported, and the surface has blocks set in a silt/clay matrix (here silt/clay is used in order to be more comprehensive than Ballantyne's (1998) silt matrix) and shows evidence for frost sorting (Figures 4(c) and 3).

Particle Size

In autochthonous blockfields, the particle size is controlled by the lithology of the underlying bedrock and by weathering

mechanisms. At the boulder scale, the joint spacing in the bedrock is the controlling factor, and larger joint spacings produce larger blocks, while smaller joint spacings produce smaller blocks, irrespective of weathering process (mechanical or chemical). Joint spacing will also control the weathering rate under any weathering regime, as smaller joint spacings provide a greater surface area of rock susceptible to water ingress. Massive lithologies and outcrops are less susceptible to weathering (Ballantyne, 1998). Analysis of the matrix sediments potentially provides a more diagnostic fingerprint regarding

the degree of chemical alteration, and thus on the weathering history. This is most applicable to coarse-grained igneous and metamorphic rocks, as sedimentary rock mineralogies are closer to equilibrium with conditions (temperature and pressure) at the Earth's surface (Bowen's reaction series). Additionally, sedimentary rocks may already contain mineral assemblages diagnostic of former weathering environments, but not those responsible for their most recent breakdown. Fine-grained metamorphic rocks may suffer similar inheritance problems.

Mechanical weathering of exposed rock surfaces and joint-controlled blocks will proceed by granular disintegration. The mode of mechanical weathering is irrelevant: it may occur through classic freeze-thaw (expansion and contraction) of *in situ* porewater, or via stressing and enhanced ice growth by porewater migration to a freezing front (segregation ice formation), or through thermal stress/shock produced by rapid surface temperature fluctuations (Hall et al., 2002). Lines of mechanical weakness are defined mostly by intercrystalline microcracks and thus exert control on the particle-size range of the fines produced. The minimum grain size in the fines is equivalent to the minimum crystal size, while larger grains are composed of multiple crystals. Mechanical weathering is unable to reduce the particle size further. Indeed, experimental studies and field evidence suggest that many lithologies are extremely resistant to mechanical weathering below the joint scale, exemplified by the preservation of striae and friction cracks on bedrock surfaces following subaerial exposures of >10 ka (Ballantyne, 1998; Lautridou and Seppälä, 1986). Thus, mechanical action tends to produce matrix sediments that are sand-sized and larger (Rea et al., 1996b).

Chemical weathering can reduce particle sizes below the crystal size of the parent bedrock, with the silt (63–2 mm) and clay (<2 mm) size fractions increasing as the degree of alteration proceeds (van Wambeke, 1962). The reduction in size is effectively the long-term result of destabilization and dissolution of the original mineral, with only a portion remaining *in situ* as a clay mineral. Based on original French terminology, Hall et al. (1989) present a tripartite granulometry classification most applicable to coarse-grained rocks, which can be used as a proxy for the degree of chemical alteration (Table 1). Although mostly applied to low-latitude

Table 1 Granulometric classification, applicable to coarse-grained rocks, indicating the different degrees of chemical weathering

Classification	Median grain size (μm)	Silt content (%)	Clay content (%)	Increasing chemical alteration
Granular grus	>1000	<15	<3	
Grus	<1000	15–25	<6	
Clayey grus	<1000	>25	>6	↓

in situ weathering profiles (Hall et al., 1989), this classification has been used to infer a dominant role for chemical weathering in the production of plateau blockfields in north Norway (Rea et al., 1996a). Figure 5(a) shows the particle-size data for two blockfield sites in North Norway, and indicates that Pit 1 (Figure 5(b)) is a type 3 clayey grus and Pit 3 (Figure 5(c)) is a type 3 grus/clayey grus (Rea et al., 1996a). Given sufficient time even in cold environments, chemical weathering can produce fines that are significantly enriched in silt- and clay-size fractions, compared with the parent bedrock.

Fine-Grained Matrix Geochemistry

The mineralogy of the weathering products is potentially a diagnostic tool for the weathering origin and thus the age of blockfields, but it must be treated with caution. Of greatest importance are the clays that result from chemical weathering processes occurring at the Earth's surface – not those produced by hydrothermal alteration or recrystallization at depth. It is also important to note that for sedimentary and metamorphic bedrock it is possible that weathering products from previous subaerial exposure may become re-exposed at the surface as a result of exhumation. For example, Fjellanger and Nystuen (2007) demonstrated a complex weathering history for quartzites on the Varanger Peninsula. During the Neoproterozoic,

Figure 5 (a) Particle-size distributions of blockfield fines. Pit 1 is defined as a clayey grus, while Pit 3 is a grus/clayey grus, based on the classification shown in Table 1. (b) Pit 1 displays a matrix-supported profile and is representative of a type 3 blockfield. Note the water in the base of the pit and the overall depth. Rockhead has not been reached. (c) Pit 3 displays a matrix-supported profile and is representative of a type 3 blockfield. Rockhead has again not been reached. Reproduced from Rea BR, Whalley WB, and Porter EM (1996) Rock weathering and the formation of summit blockfield slopes in Norway: Examples and implications. In: Anderson MG and Brooks SM (eds.) *Advances in Hillslope Processes*, pp.1257–1275. Chichester: Wiley.

subaerial weathering produced clastic kaolinite and other mixed-layer clay minerals which coated quartz sand grains. Subsequent burial, to shallow depth, produced diagenetic kaolinite and illite, which are found today on the re-exposed 'paleic-surface.'

Controlling factors on the weathering process are:

1. parent lithology, which dictates the mineralogy;
2. climate, subdivided into precipitation and temperature;
3. topography, combined with (2), controlling the water to rock contact area (drainage); and
4. age, which controls the length of time exposed to weathering.

Parent lithology and the water/rock ratio control the clay minerals that are produced, temperature controls the reaction rates, and time determines how far along a particular path the weathering sequence has reached (Velde, 1992). The importance of time must be emphasized and is highlighted in Figure 6.

Even under unfavorable conditions of low reaction intensity and low temperature (e.g., at high latitudes/altitudes), time alone may progress the chemical weathering process toward clay mineral production. However, time has significant implications for the origin of blockfields in mid- to high latitudes, as discussed below.

Some generalizations are useful for understanding the formation and presence of clay minerals, which may be found in blockfield matrix sediments. Table 2 shows the major clay mineral types and associated climates, but it must be

Figure 6 A weathering sequence shown as a function of reaction intensity and reaction progress. Given a higher reaction intensity (e.g., greater water/rock ratio), less time is required to progress from minerals through the weathering sequence. Alternatively, for a given reaction intensity, increasing age will ultimately progress the weathering process, while increasing temperature may counter a lower reaction intensity or decrease the exposure time. Reproduced from Velde B (1992) *Introduction to Clay Minerals: Chemistry, Origins, Uses and Environmental Significance*. London: Chapman and Hall.

remembered that local factors, including parent lithology, inheritance, and age, will all influence the actual minerals found in any location. Excluding dissolution of carbonate, in high-latitude/-altitude environments, low temperatures and often limited availability of moisture ensure that chemical weathering is curtailed. However, it is not absent, as surface and near-surface temperatures can be sufficient to allow chemical weathering, but the production rates are likely to be extremely low (Hall et al., 2002). This means simply that, even if hydrothermal, diagenetic, metamorphic, and exhumation of older weathering products have been excluded, the presence of clay minerals is not sufficient to interpret blockfield matrix sediments as inherited from a different (warmer) climatic regime. Rather, it is a combination of clay types and concentrations that better represent inheritance from a previous weathering climatic regime (e.g., Dahl, 1987; Fjellanger and Nystuen, 2007; Hall et al., 1989; Marquette et al., 2004; Rea et al., 1996a,b; Roaldset et al., 1982). Given that even in the coldest and driest of environments limited chemical and mechanical weathering will still occur, no matter how slowly, relict autochthonous blockfields do not really exist (Ballantyne, 2010a). It should also be mentioned that aeolian deposition could deliver clay minerals to a site, though no reports of such a source in blockfields are known from the literature (Goodfellow et al., 2008).

The application of more advanced geochemical interpretative techniques has begun to contribute to blockfield research (e.g., Goodfellow et al., 2008). These comprise a number of techniques whereby elemental mobility, elemental mass balance, and dimensionless estimates of the degree of weathering may be determined in order to elucidate *in situ* weathering activity and to enhance understanding of the potential longevity of the weathering history. Goodfellow et al. (2008) analyzed samples from two sites in the vicinity of Tarfala-tjärro, Northern Sweden. They used the isocron technique to demonstrate that there had been little movement of labile elements within the profile. This technique cross-plots elemental concentrations from the matrix and the bedrock, with scaling factors allotted to elements to ensure that they

Table 2 Idealized climate, weathering profile, and clay mineralogy relationships. It should be noted that the parent lithology, local conditions, and inheritance will control the actual weathering products found *in situ*

<i>Climate</i>	<i>Depth to rockhead (m)</i>	<i>Predominant clays</i>
Desert (hot and cold)	0.1	Mostly inherited (mica chlorite)
Semiarid steppe	1.0	Smectite (salts, carbonate concentrations, sepiolite-palygorskite)
Temperate	1.0	Illite, kaolinite, soil vermiculite, hydrated oxides (minor smectite)
Tropical wet	15	Kaolinite, hydrated iron aluminum oxides
Tropical dry	1.5	Smectite

Data from Velde B (1992) *Introduction to Clay Minerals: Chemistry, Origins, Uses and Environmental Significance*. London: Chapman and Hall.

are spread across the diagram. Immobile elements should plot on a straight line (i.e., no change in concentration between parent and weathered matrix), with elements enriched in the matrix plotting above and those that are depleted plotting below (Taylor and Eggleton, 2001). Goodfellow et al. (2008) also applied a mass balance analysis (mass of elements lost or gained by the matrix relative to the parent) to show that there had been only minor elemental losses from both the sites. Finally, they applied a chemical index of alteration (CIA – one of many possible such analyses; Taylor and Eggleton, 2001) analysis which demonstrated the absence of vertical weathering intensity (due to either limited chemical weathering and/or profile mixing due to periglacial activity, e.g., heave and sorting) and limited production of secondary weathering minerals. It also demonstrated that at least some additional matrix material had been added to the site because the CIA of the matrix was lower than that of the ‘parent’ bedrock; this was interpreted to be from up-slope.

Clast Angularity

The traditional view of cold-climate mechanical weathering is that it produces angular clast forms. However, granular disintegration in cold climates would appear to produce rounded forms (Ballantyne, 1998). Hall et al. (2002) and Boelhouwers (2004) argue that angularity of weathering products and landforms in cold climates is not universal, and in many instances rounded clasts and landforms are produced. This has important implications, as angularity of blocks and clasts cannot be taken as evidence of either a cold or a warm climate: rather, it represents a mechanical origin.

Grain-scale characteristics can be treated in the same manner as the larger material, so that mechanical grain textures are likely to be sharp and angular, while chemical signatures will etch and round grains by dissolution, alteration, and overgrowths. Visualization of blockfield matrix sediments is generally best achieved using techniques in scanning electron microscopy, and grain textures may be used as supporting evidence for weathering origin interpretations (Mellor and Wilson, 1989; Roaldset et al., 1982; Whalley et al., 1996).

Observations on half-buried clasts are extremely useful for determining the frost-heave activity in a blockfield. For example, if a clast sitting on the blockfield surface shows evidence of well-developed granular disintegration and rounding on the exposed (upper) surface, with an angular character on the subsurface, this indicates stability of the profile. In other words, the clast has been *in situ* for some considerable length of time for the granular disintegration to have developed (Ballantyne, 1998).

Age and Origin

It is important to note that the term ‘blockfield’ should only be applied as a generic descriptor of the landform and does not define genesis (age or weathering origin). There has been long-standing debate in the scientific literature regarding the age and origin of blockfields, which has focused on three potential scenarios, namely, recent (e.g., late- to postglacial; Dahl, 1966; Dredge, 1992), Pleistocene (Ballantyne, 1998; Kleman

and Borgstrom, 1990; Nesje et al., 1988), and pre-Pleistocene (Dahl, 1987; Dyke, 1993; Kleman and Stroeven, 1997; Nesje, 1989; Nesje et al., 1988; Roaldset et al., 1982).

Recent <10 ka

Of necessity, rapid formation is related to recently evolved blockfields but may also have applicability to old preserved forms, though this would be difficult to determine. Most early interpretations of blockfields assumed rapid formation based on the assumption that the last ice sheets were pervasively erosive, so any blockfields not sourced from till (Roaldset et al., 1982) must have formed during the postglacial period. Such views have been superseded with a greater understanding of ice dynamics and knowledge that glaciers and ice sheets can be entirely, or in part, cold-based and nonerosive and that distinct thermal boundaries may be represented in the landform record (Ballantyne, 2010b; Kleman and Borgstrom, 1990; Kleman and Stroeven, 1997). However, evidence exists that blockfields have formed rapidly, both in the Late Glacial and postglacial periods.

Dredge (1992) presents evidence for postglacial formation of carbonate blockfields on Igloolik Island and the Melville Peninsula, in the Eastern Canadian Arctic. Currently a permafrost climate, conditions are such that mechanical and chemical weathering (given the bedrock lithology) are active today. These assumptions are supported by field observations; for example, mudlines (linear rows of mud circles) associated with active-layer processes cross-cut 1-ka-old beach ridges (Dredge, 1992). The angular nature of the material in beach ridges up to 140 m a.s.l. has been used to cite rapid formation, potentially by freeze–thaw weathering in a shallow marine environment.

Ballantyne (1998) reports blockfields developed during the ‘Late Glacial’ in northwest Scotland between the limits of the Last Glacial Maximum ice sheet and the Loch Lomond Stadial (LLS) (Younger Dryas) ice-field limits; it should be noted, however, that some trimlines previously identified by Ballantyne and coworkers have now been reinterpreted as representing internal ice-sheet thermal boundaries, which may have implications for the formation age of some of the Scottish examples (Ballantyne, 2010b). Exposure to intense active-layer and periglacial processes was of limited duration, and formation is assumed to have ceased at the end of the LLS (i.e., there are no blockfields developed inside the limits of the LLS glaciers). Development is lithologically controlled, with thick blockfields found only on microgranite and quartzite, and only thin blockfields developed on some granites and schists (Ballantyne, 1998).

These two examples suggest that, given favorable lithologies, blockfields can develop rapidly in permafrost/periglacial climates, probably within a few millennia, becoming more developed with time (thicker). Importantly, in both examples, rapid development only occurs under cold-climate conditions, which should have an impact upon the particle-size range, quantity of fines, clay mineralogy, and clast angularity. Particle-size range should be controlled by granular disintegration, clay minerals (excluding inheritance) should be absent or representative of limited surface chemical alteration, and quantities should be low, and a type 1 openwork structure is expected,

given the limited production of fines. Account, of course, must be taken of the parent lithology; for example, Dredge (1992) reports a terminal grade of weathering products as 35% sand, 45% silt, and 20% clay, but this reflects the grain size of the original dolomitic limestone, namely, 30% fine sand, 50% silt, and 20% clay. Site 4 in Figure 7 (Ballantyne, 1998) shows a type 1 blockfield, while site 11 is a type 3 blockfield, both resulting from rapid development (Ballantyne, 1998). The relative abundance of fines at site 11 is assumed to reflect the grain size and joint spacing in the mica schist.

Pleistocene

Blockfield formation within the Pleistocene is of broad time frame, covering at least 1.8 Ma, so this hypothesis can be viewed as making more time available for weathering to progress. Given that no 'recent' blockfields show significant formation of clay minerals, it may be assumed that the major

agent of formation during the Pleistocene is mechanical weathering, with some minor component of chemical activity, presumably most intense during interglacials. Even for mid-latitude sites, based on Holocene interglacial weathering, the chemical weathering rate will be low (Goodfellow et al., 2008), although temperatures during the last interglacial were higher than the present one. It is expected that particle size will be controlled by granular disintegration, and that clay minerals (excluding inheritance) should be present but may be representative of limited chemical alteration depending upon the location, for example, high or mid-latitude (Goodfellow et al., 2008). Longer periods of exposure should produce more fines, but the size range will be controlled significantly by the bedrock grain size. Type 2 (most likely) or type 3 (lithology-dependent) profiles are expected, given the greater quantity of fines and role of frost action in sorting the profile.

This age range requires that the blockfield has survived through at least one glacial-interglacial cycle, and, provided the blockfield lies within the limits of one or more Pleistocene

Figure 7 Profiles through blockfields developed on mountains in the northwest Highlands of Scotland. Type 1 are represented by 1–6, type 2 by 7–8, and type 3 by 9–12. Reproduced from Ballantyne CK (1998) Age and significance of mountain-top detritus. *Permafrost and Periglacial Processes* 9: 327–345.

glaciation, there are implications for ice dynamics and ice sheet/glacier geometries. Blockfields may survive through glaciation either as nunataks (Dahl, 1987) in which case there may be trimlines defining a lower limit to their distribution (Ballantyne, 1998; McCarroll, et al., 1995; Nesje, 1989; Nesje et al., 1988), or beneath cold-based protective ice (Hättestrand, and Stroven, 2002; Ives, 1958; Kleman and Borgstrom, 1990; Kleman and Stroeven, 1997; Rea et al., 1996a,b; Sugden and Watts, 1977).

Pre-Pleistocene

A pre-Pleistocene age means that the blockfield has been developing for probably a significantly longer time than 1.8 Ma and has also probably experienced warmer climates than the present day. As conditions deteriorated into the Pleistocene, local high-level cirque glaciation, then regional icefields, and ultimately ice sheets grew and disappeared repeatedly in mid- and high latitudes (Kleman and Stroeven, 1997). During the onset and termination phases, the relict weathering profiles would have been exposed to intense periglacial and permafrost processes which would have moved the basal corestones upward through frost-heave mechanisms (Hättestrand and Stroven, 2002; Kleman and Borgstrom, 1990; Kleman and Stroeven, 1997; Rea et al., 1996a,b; Whalley et al., 1996). Frost-heaving of clasts through the profile will destroy any former weathering horizons, homogenizing the matrix sediments (Figure 5; Rea et al., 1996a). As chemical weathering was dominant during the initial formation, this should be reflected, to some degree at least, in the particle size and clay mineralogy of the matrix sediments. Depending upon the parent lithology and degree of alteration, the matrix sediments may be classified under any of the granulometric classes shown in Table 1 (Dahl, 1966; Rea et al., 1996a,b; Roaldset et al., 1982; Whalley, et al., 1996). Type 2 or type 3 profiles are expected (Figures 2(b), 3, 4(b, c), and 5(b, c)) unless a significant amount of fines have been removed. The matrix sediment may also contain a coarser component of Pleistocene age, derived from granular disintegration of exposed surface blocks.

Again, if the blockfield is located within the limits of any former glaciations, then it has survived intact, either by remaining unglaciated, for example, as a nunatak or enclave like the Antarctic Dry Valleys, or by protection beneath a cold-based ice cover.

A Unifying Model

As noted above, there has been long-standing debate regarding the age and origin of blockfields, with convincing evidence presented by different authors, for different sites, to support the full spectrum of suggested formation ages. Ballantyne (2010a) presented a model that eloquently unifies the pre-Pleistocene and Pleistocene models. Utilizing the sediment stripping/tor exhumation rates determined from cosmogenic exposure ages and tor relief, he clearly demonstrates that in many instances, up to a few tens of meters of sediment have been stripped from many landsurfaces which contain tors and blockfields. It is assumed that unless a landsurface has previously been completely denuded (e.g., under warm-based ice), it must have evolved from a pre-Pleistocene regolith cover,

which depending upon geographic location, lithology, and age may have had weathering fronts at considerable depths below the surface and contained substantial amounts of clays and clay minerals indicative of weathering longevity and warmer climates. Once this simple concept is established, it then follows that (Figure 8):

- if Pleistocene regolith stripping is limited, then intact roots of the saprolitic profile, including *in situ* corestones, will be preserved;
- if Pleistocene regolith stripping approaches the depth of the initial weathering front, then evidence of this will be preserved in the clay minerals and matrix particle size, but the profile is modified by periglacial frost wedging and heaving of blocks to the surface;
- if Pleistocene regolith stripping exceeds the depth of the initial weathering front, then evidence of this former profile is lost and a periglacial-derived blockfield is formed containing small amounts of clay produced by limited chemical weathering and possibly some remnant from the original profile.

This model provides a framework for interpreting the vast majority of blockfields described in the literature, resolving the apparent dichotomy of blockfields with significant quantities of evolved clays and those with limited and less evolved clays.

Implications for Ice Geometry and Dynamics

The lower limits of blockfields, if marked by a trimline, represent an important tool in paleoglaciology and provide an accurate marker of ice thickness (Figure 9). Examples include those in southern Norway (Nesje, 1989; Nesje et al., 1988) and the Scottish Highlands (Ballantyne, 1998; McCarroll, et al., 1995), although, as noted above, it has recently been suggested some of these may actually represent internal thermal, and thus erosional, boundaries. However, dating of blockfields and trimlines is a significant problem which will be discussed briefly below.

Proximity to a present-day ice mass (Rea et al., 1996a,b), spatial relationships with ice limits and ice-modified landscapes (Ballantyne, 1998; Dyke, 1993; Hättestrand and Stroven, 2002; Kleman and Borgstrom, 1990), or the presence of erratics (Ives, 1958; Sugden and Watts, 1977) provide evidence which may indicate that a blockfield has been formerly covered by ice. In such situations, it is clear that the ice cover has been nonerosive, and in all likelihood cold-based. The presence of scattered erratics presents no significant problems of interpretation, as erratics may be transported in cold-based ice (Ives, 1958; Marquette et al., 2004; Rea et al., 1996b; Sugden and Watts, 1977). However, large numbers of erratics may indicate that the blockfield is sourced from till, having been sorted sometime after deposition (Roaldset et al., 1982). Such an origin for blockfields places them in a different category from the autochthonous or para-autochthonous blockfields discussed in this article.

The juxtaposition of plateaux containing preserved relict landsurfaces including blockfields and tors, with adjacent deeply incised glacial valleys and fjords, is interpreted as a landscape of selective linear erosion. From local, through

Figure 8 A model for autochthonous blockfield formation illustrating the various levels of modification resulting from preglacial regolith stripping and Pleistocene cold-climate weathering. WF, weathering front. Stage 1 represents the preglacial situation where there is deep chemically weathered saprolite cover. During Stage 2 in the early Pleistocene, changed conditions see the initiation of saprolite stripping (with tor exhumation) and concomitant concentration of core stones with the rate of surface lowering reduced once a corestone lag 'armors' surface. Stage 3 follows continued stripping and increased modification by permafrost/periglacial weathering, with the weathering front depth controlled by the maximum depth reached by either seasonal freezing or active-layer melting. The matrix will have a mixed mineralogy and particle sizes comprising some relict saprolite and some granular disintegration products. Stage 4 is reached when surface lowering has removed all traces of the former weathering, the profiles are entirely dominated by frost-wedged and heaved boulders with a granular disintegration-derived coarse matrix. There may be traces, or minor amounts, of clay minerals present but these are the products of interglacial weathering. Modified from Ballantyne CK (2010) A general model of autochthonous blockfield evolution. *Permafrost and Periglacial Processes* 21: 289–300. <http://dx.doi.org/10.1002/ppp.700>.

regional, to full ice-sheet glaciation, ice in the valleys is more likely to be warm-based, due to factors such as lower elevation, thicker ice, and increased ice discharge. The corollary is that on the intervening plateaux/interfluvies ice remains thinner, colder, and less or nonerosive (Rea et al., 1996b; Sugden and Watts, 1977). Through this topographic control, preservation of landsurfaces and extensive erosion can coexist. From the

model presented in Figure 8, it is clear that these landsurfaces are not truly relict or preserved (e.g., if 10 m of regolith has been stripped). However, they do represent a guide to a preglacial surface (though not necessarily one graded to a former sea level) and a marker for interpreting evolution of a landscape of selective linear erosion. Preservation–modification relationships without vertical incision have also been found

Figure 9 Trimline with blockfield above, delimiting former glacier ice thickness, Mount Hoffmann, Yosemite, California, USA. Photograph by C. K. Ballantyne.

for the centers of ice sheets and ice caps in parts of Scandinavia and the Canadian Arctic and are also related to basal thermal boundaries (Dyke, 1993; Hättestrand and Stroven, 2002; Kleman and Borgstrom, 1990; Kleman and Stroeven, 1997).

Dating Blockfields

While the age of blockfields is of major interest, its determination is complicated by the likely duration of protection/preservation by cold-based ice. Clay mineralogy has traditionally been used as a proxy for longevity and aggressiveness of the weathering environment, though, as cautioned by Goddard (1989), care must be taken with this approach. The clay mineral species, the quantity of clays, and potential for a non-*in situ* weathering origin, for example, bedrock or exhumed sources (Fjellanger and Nystuen, 2007) or aeolian deposition, must all be assessed before making an age interpretation. For example, there is uncertainty regarding the age of gibbsite in montane soils in Scotland; is it truly pre-Pleistocene or the result of interglacial weathering through the Pleistocene (Ballantyne, 1998; Hall et al., 1989)? Even when the evidence is convincing that the clay mineralogy represents a long-term *in situ* history, this is generally poorly constrained (Rea et al., 1996a,b; Roaldset et al., 1982).

The development of cosmogenic dating represents a major breakthrough in the study of relict landsurfaces. From the discussion above, it seems that there are blockfields in mid- to high-latitude locations that have experienced considerable longevity in the landscape, with little modification, despite repeated coverage during Pleistocene glaciations. Stone et al. (1998) used ^{36}Cl and ^{10}Be to date sites above and below trimlines in northwest Scotland. The authors clearly demonstrated the exposure age differences between the sites, suggesting that the older ages (22.6–70 cal ka BP) above the trimline indicate exposure throughout the last glaciation and the younger ages below the trimline (13.9–17.6 cal ka BP) indicate erosion and resetting of the cosmogenic clock. However, complications exist in interpreting exposure ages, as there are inheritance effects associated with multiple exposure–burial events, which are likely to affect the measured age (Ballantyne, 1998; Bierman et al., 1999; Marquette et al., 2004; Stone et al., 1998). The use

of cosmogenic radionuclide ratios with different half-lives (e.g., $^{26}\text{Al}/^{10}\text{Be}$) must be used to indicate whether single or multiple phases of burial–exposure have occurred. Bierman et al. (1999) used paired ratios to interpret minimum total histories for glaciated bedrock surfaces on Baffin Island up to 735 ka (Table 3). Dating exposure ages/histories of tors, blockfield blocks and erratics can also help constrain the dimensions and duration of former ice cover (e.g., Marquette et al., 2004). Additionally, combining paired ratios with exposure history proxy records derived independently may further improve the modeling of exposure histories (e.g., Phillips et al., 2006; Stroven et al., 2002). Table 3 presents some example ages that offer convincing support of the concept of longevity of blockfields and tors in repeatedly glaciated landscapes.

Small et al. (1997, 1999) determined bedrock erosion and regolith production rates for weathering-rate-limited summits in some mountain ranges in western United States. Their data indicated well-mixed profiles due to active frost-heaving processes. They could find no evidence for former ice cover, and they inferred that weathering rates beneath the regolith (blockfield) were almost double those of bare rock ridges and tors. The summit flats, crest ridges and tors were thought to have evolved over the past 2–3 Ma by more rapid weathering and surface lowering beneath the blockfield and reduced weathering on crest ridges and tors. Surface lowering was accomplished by slow creep of material down to, and over, the sides of the summit flats (Anderson, 2002). The results of this work are interesting, as they question the widely held interpretation that these summits represent former land surfaces (though not necessarily graded to a former base level). The model remains to be tested in other localities where there is clear evidence of a former ice cover (which could reduce considerably the time for weathering and mass movement) and on blockfields where bedrock lithological changes are retained within the blockfield. For example, where an underlying bedrock lithological boundary is retained within the overlying blockfield, and provided that the boundary is not oriented directly downslope, this indicates no removal of material by mass movement.

Conclusion

Long-standing debates regarding the age of blockfields are now, through the advent of new dating techniques such as cosmogenic nuclide dating, beginning to be resolved. Cosmogenic dating has confirmed age ranges (from blockfield and/or tors, see Table 3) from the recent through to 845 ka (Fabel et al., 2002), representing long-term evolution and ‘stability’ within the landscape. However, cosmogenic nuclide dating cannot provide all the answers, as multiple burial–exposure histories make interpretation of ages complex and the heaving of fresh boulders to the surface may mean a range of exposure ages are found, and any date can be considered a minimum (Bierman et al., 1999; Marquette et al., 2004). Geomorphology and clay mineralogy remain vital for understanding the origin of blockfields in terms of their weathering origins. The history of blockfields can provide data on glacial, interglacial, and preglacial earth-surface processes and an integration of these through time, and also provide marker surfaces from which to quantify glacial incision and rates of landscape

Rock Glaciers and Protalus Forms

Definition and Distribution

Perennially frozen debris in cold mountains may, under the force of gravity, form so-called rock glaciers, which often show a shape similar to that of lava streams (Figures 1–7). Formerly, rock glaciers were often thought to be a form of debris-covered glaciers, which led to the term ‘rock glaciers.’ Since then, a number of fundamental differences between rock glaciers and glaciers related, for example, to their thermal conditions and mass balance have been established. This has led to the use of the term ‘rock glaciers’ to distinguish their individual character from that of glaciers (Barsch, 1996). This meaning of ‘rock glacier’ is used in this article, although the equivalent term ‘rock glacier’ is also established in the scientific literature.

Rock glaciers occur in most cold mountains of Earth. These include the Andes, the Rocky Mountains, the European Alps, the Pyrenees, the Caucasus region, the Central Asian mountain ranges, the Siberian mountain ranges, the Himalayas, the New Zealand Alps, Greenland, Antarctica, and the Arctic and Antarctic Islands (Barsch, 1996; Martin and Whalley, 1987). Rock glaciers often occur in similar, though slightly colder and drier climatic settings as glaciers (Brazier et al., 1998; Humlum, 1998). It is also speculated, on the basis of space imagery, that rock glacier-like features exist on Mars. Under suitable climatic and topographic conditions – that is, mean annual air temperatures between roughly -2 and -6 °C, total annual precipitation between 500 and 1500 mm, and sufficient debris production from rock walls (Etzelmueller and Frauenfelder, 2009) – rock glaciers may be abundant, with their number often exceeding that of glaciers in the same mountain range, but with significantly smaller areas for individual rock glaciers.

Thermal Conditions

A fundamental characteristic of rock glaciers is their thermal state (Haeberli, 2000; Haeberli et al., 2006). They consist of a perennially frozen mixture of debris and ice, that is, their long-term existence requires permafrost conditions. Permafrost is defined as lithospheric material with year-round negative ground temperatures (Harris et al., 2009). A surface layer of depth ranging from several decimeters to meters thaws during summer and is termed the ‘active layer.’ Below the ‘permafrost table’ – the lower boundary of the active layer – the temperatures in the ‘permafrost body’ remain negative down to the ‘permafrost base’ (Haeberli, 1985; Haeberli et al., 2006; Vonder Muehl et al., 2003). Thus, the mixture of debris and ice within the permafrost body remains frozen throughout the year, possibly over centuries and millennia if the thermal conditions do not change substantially over time.

The surface layer of rock glaciers consists of debris with typical diameters ranging from several centimeters or decimeters to meters, depending on the geological setting, weathering

conditions, and processes of debris reworking. If this layer is at least as thick as the local active layer, that is, the seasonal thaw depth under the specific local conditions, then positive ground temperatures during summer cannot reach down to the ground ice containing permafrost body. Thus, ground ice can persist for very long periods of time (Haeberli et al., 2006).

From the aforementioned principle, it becomes clear that the long-lasting persistence of the frozen core within a rock glacier requires permafrost conditions. The difference between rock glaciers, dead ice, or debris-covered glaciers can thus be described by the thermal state of the material.

Transformations between these conditions are possible. For instance, glacier ice under an insulating debris cover and lying within a permafrost environment is subject to seasonal ice melt, though substantially damped, wherever the debris cover is thinner than the local seasonal thaw depth. The ice body will continuously lose mass if not compensated by the advection of glacier ice. The resulting meltwater, and with it the contained energy, can percolate into and warm the underlying ice body. If the ice body contains sufficient debris, this material will accumulate at the top of the ice core, leading to a thickening of the debris cover. When the thickness of the debris cover equals the local seasonal thaw depth, the underlying ice is protected against surface melt unless lateral processes such as erosion occur. Thus, the debris within rock glaciers may stem from periglacial and glacial processes and sources, and the rock glacier ice content may originate, for example, from refreezing rain and meltwater, glaciers, buried ice and snow patches, or combinations thereof (Haeberli and Vonder Muehl, 1996; Haeberli et al., 2006). Temporal transformations and spatial transitions between rock glaciers, debris-covered glaciers or dead ice, and ice-cored moraines are often found in nature.

Being closely related to permafrost conditions, rock glaciers indicate the existence of discontinuous or continuous mountain permafrost on a regional scale (Harris et al., 2009). The lower boundary of regional rock glacier distribution, however, does not generally coincide exactly with the lower boundary of permafrost distribution (Frauenfelder et al., 2008). Rock glaciers may end above the regional permafrost limit due to topographic constraints, limited debris supply, or insufficient time to fully develop. However, the coarse debris cover on top of a rock glacier favors ground cooling due to enhanced heat transfer to the atmosphere, allowing rock glaciers to extend downslope below the regional permafrost limit.

Composition

The composition of rock glaciers is investigated by boreholes and geophysical surveys, particularly geoseismics, direct current resistivity soundings, or georadar. So far, only a few boreholes have been drilled through rock glaciers (Arenson et al., 2002; Haeberli et al., 1998, 2006; Harris et al., 2009; Hoelzle

Figure 7 Rock glacier in the Tien Shan. Photograph by S. Titkov.

et al., 1998; Steig et al., 1998) and, therefore, the extent to which their findings can be generalized is uncertain. All the drillings have revealed a surface layer of ice-free debris with a thickness on the order of meters (active layer; Haeberli et al., 2006). The underlying layer, a few tens of meters thick, consists of a frozen mixture of ice and debris with an ice content ranging from close to 100% to a few tens of percent. In rock glaciers where deep core drilling was conducted, a third layer of frozen coarse debris with little ice content was encountered. This layer is believed to originate from surface blocks that had fallen over the rock glacier front and were overridden by the advancing rock glacier (see section 'Kinematics and Advance'; Haeberli et al., 1998).

In the rock glaciers with deep core drillings, a meter-thick layer of sand-rich ice was found within the second ice-rich layer, at depths between 15 and 30 m. The majority of the horizontal deformation within the rock glacier was found to be concentrated in these sandy ice layers (see section 'Kinematics and Advance'; Arenson et al., 2002).

Many geophysical soundings have confirmed the general layering and composition described earlier for other rock glaciers (Berthling et al., 1998, 2000; Bucki et al., 2004; Isaksen et al., 2000). In addition, some high-resolution soundings have revealed fine layers within the ice-rich subsurface layer. These microlayers were attributed to seasonal sequences of snow/ice and debris deposition at the rock glacier surface, and their continuous incorporation and deformation within the creeping body (Berthling et al., 2000; Humlum et al., 2007).

Kinematics and Advance

Besides their special thermal conditions, the second fundamental characteristic of rock glaciers is their mode of displacement. Given sufficient terrain slope, the ice–debris mixture within a rock glacier deforms under the force of gravity and the stress of the vertical column. The resulting surface speeds on rock glaciers may be several meters per year (Kääb et al., 2003; Kaufmann and Ladstädter, 2002; Figure 8). Rock glacier surface speed depends, among other things, on surface slope, composition and internal structure, thickness of the ice-rich body, and ground temperature (Haeberli, 1985). The observed minimum surface speeds of a few millimeters per year are not

Figure 8 Surface displacement vectors on Murtel rock glacier, Swiss Alps, measured from air photographs of 1987 and 1996.

limited by the deformation process itself, but rather by the available measurement technique (e.g., digital photogrammetry, global navigation satellite system, radar interferometry; Lambiel and Delaloye, 2004; Strozzini et al., 2004).

A coherent ice content within rock glaciers leads to the lateral transfer of stresses and thus to a coherent velocity field. Owing to effects such as lateral friction and variations in viscosity, the highest horizontal speeds on a rock glacier are usually found along its centerline. In the few available boreholes through rock glaciers, the horizontal deformation was concentrated in horizontal layers some decimeters to meters thick, rather than distributed throughout the body of the rock glacier, with a clear parabolic variation of horizontal speeds with depth such as found for glacier ice (Arenson et al., 2002).

The basic concept of mass transport within a rock glacier can be derived from the characteristic thermal and kinematic conditions: debris is deposited at the rock glacier surface, either directly from weathering processes at the headwall or from other secondary sources, in most cases presumably glaciers and avalanches (Humlum, 1998; Humlum et al., 2007). Together with ice from different sources (see section 'Thermal Conditions'), this mass represents the mass input to the rock glacier system. Following a basic law of fluid dynamics, the surface debris is transported downslope, with the highest creep speeds at the rock glacier surface. The advected surface material then falls over the steep rock glacier front. The grain-size sorting along the frontal slope occurring during this process leads to the typical appearance of rock glacier fronts. The surface debris that accumulates at the front is then overridden by the advancing rock glacier and again incorporated into its base, in a 'caterpillar' or 'conveyor belt' fashion (Kääb and Reichmuth, 2005; Figure 9). On account of their nonice sediment content

Figure 9 Development stages and structure of an idealized rock glacier. Particle-size sorting on scree slopes concentrates finer particles on the upper slope sections (1) that become supersaturated with ice and start to deform at higher rates than coarser particles, which are not ice-supersaturated, at the slope base (2). Further debris from the headwall accumulates preferentially on the resulting ramp (2) and rafts downslope above the creeping frozen body (3). This blocky upper layer is transported over the rock glacier front, overridden, and eventually reincorporated into the rock glacier as its basal layer (3), unless debris falls over a terrain ridge and thus leaves the rock glacier system (4).

and thermal conditions, rock glaciers, in contrast to glaciers, cannot retreat. In the case of a total cessation of mass supply, a rock glacier will remain stagnant in its horizontal extent, but it will not retreat. The main process of mass loss is the melt-out of ice at the rock glacier front, where the thermally protecting debris cover becomes thinner than the thaw depth due to frontal erosion. In addition, the frontal grain-size sorting leads to smaller grain sizes in the upper part of the front, which reduces the insulation effect in comparison to the coarser debris at the rock glacier surface. Further processes of mass loss of rock glaciers include evacuation of debris, erosion and rockfall over steep terrain, debris flows, or fluvial and coastal erosion. Owing to the melt-out of ice, the potential loss of nonice debris, and the decrease of horizontal speeds with depth, the advance rate of rock glaciers is significantly smaller than their surface speed. Advance rates measured so far range from a few centimeters to decimeters per year.

Shape and Surface Morphology

Rock glaciers can be up to several hundred meters wide and a few kilometers long. Their altitudinal extent may attain several hundred meters, and their thickness may attain several tens of meters. Their overall shape and extent reflects the creep of the

mass, usually down the steepest slopes. The ratios between rock glacier length and width vary significantly, with values both above and below 1. The latter ratio reflects a number of internal conditions such as viscosity, and external factors such as topography or mass supply.

Many rock glaciers show a characteristic surface morphology consisting of transverse and/or longitudinal ridges and furrows. This morphology, in addition to the overall shape, makes rock glaciers resemble lava streams. So far, little is known about the origin of the rock glacier surface morphology.

According to the main hypotheses, the formation of transverse ridges and furrows on rock glaciers might be attributed to (a) external factors, such as variations in debris input or climate conditions; or (b) internal factors, such as the dynamic evolution of ridges under compressive flow, or disturbance propagation from differential movement of discrete layers. In addition, it is unknown whether (c) transverse ridges and furrows represent dynamic structures, for example, forming from emergence under compressive flow regime (i.e., active formation); or (d) if these forms are thermally derived due to, for instance, differential melt (thermokarst) or frost heave processes (i.e., passive formation). It is important to note that these four elements of hypotheses do not necessarily contradict one another. One possible process might enhance the other, or a combination might be necessary for the formation of

microtopographic structures. A number of studies suggest that compressive flow is a major process involved in the formation of transverse ridges (Kääb and Weber, 2004).

The high thermal inertia of rock glaciers allows these frozen bodies to continuously deform and preserves their topography over centuries and millennia (Haeblerli, 2000; Kääb et al., 2003). In addition, the debris content and the ice-free, blocky active layer of rock glaciers contribute to the conservation of surface features even over periods of ice melt. The surface topography of rock glaciers cumulatively reflects the dynamic history and thus, in a complex way, their present and past internal conditions and environment.

Activity and Age

The degree of activity of rock glaciers is usually classified into three different types: (i) active, (ii) inactive, and (iii) relict (Ikeda and Matsuoka, 2002). It should, however, be noted that this classification is a theoretical concept. The transition between the three stages is actually continuous.

Active rock glaciers have a coherent core of ice-rich frozen debris, the deformation of which leads to the rock glacier creep, with rates of several centimeters to meters per year. The permafrost conditions of the body are intact, with perennially negative ground temperatures throughout the entire column, except for the seasonally thawed active layer. The continuous creep and related debris transport along the surface leads to the characteristic steep front with freshly exposed fines in the upper part and coarser debris in the lower part, vertically sorted by grain size due to debris fall along the front (see section 'Kinematics and Advance'). The continuous deformation of the rock glacier surface, rotation and possibly related uplift of individual blocks, and the outwash of fines toward the permafrost table allow only a few specialized plant species to grow and prevent lichens from reaching great age and size (Burga et al., 2004; Haeblerli et al., 1979; Sloan and Dyke, 1998).

Inactive rock glaciers have no coherent ice core and thus no coherent velocity field due to the lack of stress transfer. They show no significant horizontal speed, except perhaps local movement, for example, due to thermokarst processes, patches of ice-rich ground, or erosion processes. Inactive rock glaciers contain a thinner permafrost body and a thicker active layer than active ones (see section 'Environmental Change and Climatic Significance'). They can be transitional forms between active and relict rock glaciers. However, indications have also been found that active rock glaciers might become inactive for certain periods – for example, due to climatic changes – but reactivate after environmental conditions become suitable again. Owing to their kinematic inactivity, inactive rock glaciers or inactive parts of rock glacier complexes usually show more vegetation cover, and more and larger lichens compared to active rock glaciers under a similar environmental setting. In particular, the frontal parts with fines exposed are preferred locations for the invasion of vegetation. Owing to the lack of material supply toward and over the front, erosion is able to reduce the frontal slope.

No permafrost or ice is present within relict rock glaciers. On account of this volume loss of excess ice, rock glacier sections with formerly higher debris content, such as ridges

and the rock glacier margins, are elevated above the rock glacier sections with formerly higher ice contents (Figure 5); thus, the original debris concentration of the active phase is still reflected in the surface topography. The characteristic ridges on rock glaciers can often also be recognized on relict rock glaciers. Similarly, the frontal zones, which in active rock glaciers contain less ice, become visible as terminal ridges. Relict rock glaciers might be covered by dense vegetation, even trees. In some rock glaciers with clear relict characteristics, patchy permafrost and ground-ice occurrences and even gravitational movements on the order of millimeters per year have been found, pointing to continuous transitions between the stages of rock glacier activity (Strozzi et al., 2004).

A number of studies have shown that the age of active rock glaciers is on the order of some to many millennia. The dating methods used range from surface dating techniques (Frauenfelder et al., 2004; Laustella et al., 2003), ^{14}C dating of organic material recovered from boreholes (Haeblerli et al., 1999), flowline calculations (Frauenfelder et al., 2004; Kääb et al., 1997, 1998), and lichen measurements (Haeblerli et al., 1979; Sloan and Dyke, 1998) to paleoclimatic considerations and numerical models (Frauenfelder et al., 2001, 2008). In the European Alps, today's relict rock glaciers are believed to have formed during the last Late Glacial period, though much older forms might exist at places where the climate conditions permitted continuous evolution, and glaciations did not interrupt this evolution.

Environmental Change and Climatic Significance

Rock glaciers are intimately dependent on their geoecological environment (Barsch, 1996). Thus, changes in these conditions have a potentially strong effect on the rock glacier system. Millennium-scale climatic changes – for example, temperature shifts such as between the Last Glacial Maximum, the Late Glacial period, and the Holocene – affect, among others, the thermal conditions, and the production and availability of debris. An increase in ground temperatures, possibly above the 0°C threshold, and/or a reduction of headwall weathering and rockfall onto underlying rock glaciers (Olyphant, 1987) are, for instance, most likely responsible for the decline in activity of rock glaciers at the beginning of the Holocene. Similarly, the atmospheric warming trends since the end of the Little Ice Age observed in most cold mountain regions may be responsible for the recent decay of rock glaciers. Indeed, the altitudinal belts where active, inactive, and relict rock glaciers are found suggest that temperature changes are an important driver of changes in rock glacier activity (Frauenfelder et al., 2001, 2008).

Significantly less well investigated, but potentially of similar importance to temperature, is the influence of long-term changes in precipitation regime. Related changes in mass supply or ground temperature may also be due to spatiotemporal changes in snow cover. Changes in the climatic regime may also indirectly favor or hinder rock glacier development. Thus, rock glaciers may be overridden by glaciers in times of climate change or rock glaciers may develop or recover at locations previously occupied by glaciers (see section 'Thermal Conditions'; Kääb and Kneisel, 2006; Maisch et al., 2003).

As yet, too little is known about the exact climatic significance of rock glaciers in order to use them reliably for paleoclimate reconstruction (Brazier et al., 1998; Frauenfelder et al., 2001; Humlum, 1998). The typical climate of modern active rock glaciers seems similar to the conditions found at the equilibrium line altitude of modern glaciers, though it is somewhat drier. Thus, the altitudinal belts where active, inactive, and relict rock glaciers are found can be used as proxies for paleoclimatic conditions that were suitable for active rock glaciers to develop (Frauenfelder et al., 2001). Such reconstruction is, however, substantially complicated by the fact that rock glacier evolution depends not only on climatic conditions, but also on debris supply and interactions with glaciation. For instance, insufficient debris production may inhibit formation of a rock glacier under otherwise suitable geoecological conditions. Or, the topographic and local climate conditions may favor a glacier to occupy the potential geoecological niche of a rock glacier. In addition, former rock glacier forms may have been removed by glacial erosion or covered by modern glaciers. As a result, reconstruction of ancient rock glaciers and their paleoclimate requires the consideration of the complete and complex spatiotemporal history of periglacial, glacial, and mass-wasting processes throughout the existence of the rock glaciers investigated (Frauenfelder et al., 2001; Maisch et al., 2003).

Geostatistical investigations on the basis of surface velocity measurements and climatic parameters, laboratory tests, and numerical modeling show that the deformation rate of rock glaciers is dependent, among other factors (e.g., slope, composition, or thickness), on the ground temperature (Kääb et al., 2007). Warmer rock glaciers show, in general, higher surface velocities than colder ones do. Consequently, ground-temperature warming as a result of atmospheric warming or changes in snow cover is expected to increase rock glacier deformation. Indeed, early investigations confirm a significant recent acceleration of many rock glaciers in the European Alps where an air temperature increase of close to +1 °C has been observed since the 1980s (Kääb et al., 2007).

From theoretical considerations, rock glacier permafrost will react in three stages to atmospheric warming (Haeberli, 1992): (i) increase in seasonal thaw depth (i.e., active-layer thickness), (ii) ground-temperature warming, and (iii) thermal adjustment toward a new thermal equilibrium accompanied by reduced thickness of the permafrost body (descending permafrost table and rising permafrost base).

Introduction

Beringia represents the largest contiguous area of the Arctic that remained unglaciated during the late Pliocene and Pleistocene. [Hulten \(1937\)](#), the Swedish biogeographer, invoked the concept of Beringia to explain the distribution of Arctic and boreal plants around the Bering Strait. He originally considered Beringia to include only the area of the continental shelf exposed when lowered sea level connected eastern Asia with North America. Today, Beringia is considered more broadly to extend from the Taymyr Peninsula through Alaska to the Yukon Territory, united by aspects of the cold-adapted flora and fauna of the region and the lack of glaciation. This area was located between the Eurasian Ice Sheet to the west and the Laurentide and Cordilleran ice sheets to the east ([Figure 1](#)). Extreme continental climate conditions were connected to the presence of a largely exposed continental shelf, a likely perennial Arctic sea-ice cover, and the existence of large ice sheets to the east and west. By virtue of the lack of glaciation, much of Beringia preserves an exceptional sedimentary record of Pleistocene environmental change.

Across this broad region, vast tracts of ice-rich and largely fine-grained sediments are present. These deposits are found in the Arctic and Subarctic areas of Beringia, and locally exceed 50 m in thickness. The deposits, owing to the presence of permafrost, preserve a diversity of exceptional paleoenvironmental archives, including mammals (e.g., [Guthrie, 1990](#)), paleobotanical remains (e.g., [Gitterman et al., 1982](#)), ancient DNA (e.g., [Shapiro and Cooper, 2003](#)), and relict ice (e.g., [Kaplina and Lozhkin, 1984](#)), and host a globally significant, and potentially vulnerable, reservoir of organic carbon (e.g., [Zimov et al., 2006](#)). While many aspects of their composition and paleoenvironmental history are agreed upon, details of their formation lack consensus, particularly regarding the strict role of eolian processes. These differences are most pronounced among workers in western Beringia (Siberia), while in eastern Beringia (Alaska and Yukon), a general consensus exists. This article reviews the history of research, terminology, characteristics, and differing ideas on the formation of the ice-rich deposits and their paleoenvironmental significance.

Terminology

The terminology for the ice-rich, syngenetically frozen deposits varies across Beringia. These deposits are often referred to as 'Ice Complex' (in Russian: *ledovyy kompleks*) or 'Yedoma' in Siberia, while in North America, other terms such as 'muck' or retransported silt could be partially considered as equivalent terms ([Froese et al., 2009](#); [Péwé, 1975](#); [Shur et al., 2004](#)).

[Solov'ev \(1959\)](#) first defined Ice Complex as frozen deposits of various age, composition, genesis, and thickness, with numerous ice wedges. Ice Complex deposits of late Pleistocene age are widely distributed on the East Siberian coastal plains (Lena-Anabar, Yana-Indigirka, and Kolyma lowlands) as well as on the New Siberian Archipelago, but they also occur in more southerly regions of East Siberia along large river valleys ([Figure 1](#)).

According to [Sher \(1997\)](#), at least three different meanings of the term 'Yedoma' exist in the Russian literature: (1) a 'Yedoma surface' in the geomorphic sense, (2) a 'Yedoma Suite' in the stratigraphic sense, or (3) a cryolithological feature implying a special kind of frozen sediment, widely distributed in Beringia ('cryolithology' is a Russian term, not widely used in North America, for the study of the genesis, structure, and lithology of frozen earth materials; [van Everdingen, 1998](#)). The latter concept of Yedoma is the one used in this article, encompassing distinctive ice-rich silts and silty sand penetrated by large ice wedges, resulting from sedimentation and syngenetic freezing, and driven by certain climatic and environmental conditions during the late Pleistocene. The term 'Ice Complex' is often used synonymously with 'Yedoma' in this sense.

The term 'Yedoma' was originally used in the geomorphic sense to describe the hills separating thermokarst depressions in northeastern Siberia, especially in the Yana-Indigirka and Kolyma lowlands (e.g., [Tomirdiario, 1996](#)). These surfaces were considered to be former accumulation plains, composed of late Pleistocene Ice Complex deposits, cross-cut to varying extents by thermokarst basins. In this sense, Yedoma can also describe a periglacial relief type formed by thermokarst processes ([Solov'ev, 1959](#)).

Initially, the stratigraphic term 'Yedoma Suite' was adopted for middle Pleistocene horizons in the northeastern Siberian lowlands ([Vas'kovsky, 1963](#)). Based on cryolithological, paleoecological, and geochronological studies at the key site of Duvanny Yar on the lower Kolyma River ([Figure 1](#)), the stratigraphic position of the 'Yedoma Suite' was considered to be only late Pleistocene ([Sher et al., 1987](#)). The upper late Pleistocene horizon of Duvanny Yar represents the stratotype of the 'Yedoma Suite' (e.g., [Zanina et al., 2011](#)), recorded by a 40- to 50-m-thick Ice Complex sequence that is characterized by heterogeneous gray-brown sandy silt with a layered cryostructure and syngenetic ice wedges up to tens of meters high. The sediments contain grass roots and lenses of fine-grained plant detritus as well as paleosols ([Zanina et al., 2011](#)). Fossil teeth and bones of the late Pleistocene megafauna are common ([Sher et al., 1979](#)). Radiocarbon dates from Duvanny Yar suggest that much of the Ice Complex formed during the late Pleistocene from ca. 40 and 13 ka (^{14}C) BP ([Vasil'chuk et al., 2001](#)).

Figure 1 Distribution of ice-rich permafrost deposits in Arctic and Subarctic lowlands in the region of late Pleistocene Beringia (according to Romanovskii, 1993, for Siberian Ice Complex; Wolfe et al., 2009, for North American loess; Ehlers and Gibbard, 2003, for LGM Glaciation; and Brown et al., 1997, for ground ice content).

In North America, where the research history of ice-rich deposits is closely related to placer gold-mining activities, they are often given the name ‘muck’ as they are a common overburden for gold-bearing fluvial deposits (Fraser and Burn, 1997; Péwé, 1975). However, the term ‘muck’ originates from the gold mining vernacular and is generally not used in a strict genetic or stratigraphic sense, and thus, it is not restricted to late Pleistocene ice-rich deposits. For example, Péwé (1975) indicated that ‘muck’ can also encompass Holocene ice-rich silts, which would be inconsistent with Yedoma as commonly defined. In recent work, the term ‘muck’ is therefore not frequently used, but instead these deposits are typically referred to as simply ice-rich silts or perennally frozen silts, emphasizing both their typical grain size and the presence of permafrost.

In North America, syngenetic ice-rich silt deposits, thought to be broad equivalents to the Siberian examples, occur in lower segments of the Arctic Foothills, in the northern part of Seward Peninsula, in numerous areas in Interior Alaska (Kanevskiy et al., 2011), and the Klondike region of Yukon Territory (Froese et al., 2009). The Klondike sites, by virtue of the gold-mining activities, have created excellent exposures for study (Figure 2). Similar to the Russian examples, Yedoma deposits in Yukon and Alaska are dominated by silt-sized particles, abundant organic matter, ice-rich syngenetic permafrost, and ice wedges and may reach 40 m in thickness. These deposits, when wet, are commonly nearly black in color from the abundant organic matter. Perhaps their most distinctive property, however, is the pungent odor they give off from the incompletely decomposed organic matter that is exposed

Figure 2 Syngenetic ice wedges with full and partial thaw surfaces. The presence of shoulders on the ice wedges (white arrows) indicates the position of the paleoactive layer and the nature of episodic sedimentation of the loessal silts on the surface of an ice-wedge polygonal ground network; to either side of the shoulders, some ice wedges are fully truncated at these levels. Sediments date to ca. 30 ka BP, Quartz Creek, Klondike area, central Yukon. Photo shows a vertical section ca. 5–6 m high. Photograph by D. Froese.

as they thaw. Although these deposits are largely of late Pleistocene age, the presence of distal, dateable volcanic ash (tephra) within some of them indicates a middle Pleistocene age (Froese et al., 2008, 2009; Reyes et al., 2010).

Following Sher (1997) and Kanevskiy et al. (2011), this article uses the term ‘Yedoma’ to describe ice-rich syngenetic permafrost that developed extensively under late Pleistocene

cold-climate conditions in unglaciated regions of Eurasia and North America.

Distribution

Yedoma deposits are widely distributed across Beringia (Figure 1). In eastern Siberia, their presence in lowlands is reflected in the modern distribution of thermokarst lakes developed on ice-rich permafrost (Figure 3). Thermokarst depressions with lakes and thermoerosional valleys shape the modern lowland relief and dissect remnants of late Pleistocene accumulation plains into Yedoma hills and uplands. Other indicators of the presence of Yedoma deposits are thaw slumps on coastal bluffs several hundred meters wide and several tens of meters deep (Figure 4), lake shores, and river banks. These sites

expose thermokarst mounds as well as large ice wedges 2–5 m wide and up to tens of meters high. These ice wedges, associated sediments, and thermokarst mounds (Figures 5 and 6) are parts of former polygonal ice-wedge systems that developed over long time periods. Generally, these exposures are formed by active thermoerosion and slumping of ice-rich permafrost, exposing sediments and ground ice in rapidly retreating steep bluffs and terraces, and allowing access to still-frozen sediments in vertical profiles.

The distribution of Yedoma in Northeast Siberia relates to a number of distinct geomorphological settings. One type of setting fringes low-elevation coastal mountains, which served as the main sediment sources for Yedoma. Heavy-mineral studies suggest a dominantly local origin for the sediments rather than long-distance transport of the silts which make up the main clastic component of Yedoma. Gently inclined

foreland accumulation plains underlain by widespread ice-wedge polygon systems were the original landscape for the accumulation of Yedoma deposits in the North Siberian lowlands during the late Pleistocene. A second geomorphologic setting in the hinterland of Yedoma areas comprises separate bedrock elevations (100–400 m high), for example, the granite domes on Bol'shoy Lyakhovsky Island (New Siberian Archipelago) and Cape Svyatoy Nos (Laptev Sea), and short fault ranges as found on Bel'kovsky, Stolbovoy, and Kotel'ny islands of the New Siberian Archipelago. These elevations are often shaped by cryoplanation terraces (**Figure 7(a)**) and framed by cryopediment areas, indicating strong periglacial weathering processes (**Figure 7(b)**). A third setting is found in extended lowland areas further away from mountain ranges. Although these distal areas are currently dominated by large and numerous thermokarst basins and lakes, Yedoma hills are commonly present between them, indicating their former widespread occurrence, such as in the Yana-Indigirka lowland. Yedoma deposits are also present in Central Yakutia in terraces of the lower parts of large mountain valleys.

All aggradational landscape types where Yedoma occurs are characterized by large, relatively flat surfaces with low hydrological gradients that are conducive to the long-term formation of syngenetic ice-wedge polygon systems. Poorly developed drainage in the late Pleistocene environment of Beringia, with its cold-arid climate, was presumably an important factor for Yedoma formation. It is likely that accumulation of Yedoma deposits also took place on vast areas of the Beringian shelf that were exposed during the late Pleistocene ([Romanovskii et al., 2000](#)).

Broad equivalents to Siberian Yedoma also occur in the Arctic and Subarctic regions of unglaciated Alaska and Yukon, or eastern Beringia. In tundra areas of northern Alaska,

Photographs by S. Wetterich and H. Meyer, AWI Potsdam.

Figure 8 Grain-size distribution curves from Yedoma deposits of different sites in the Laptev Sea region according to Schirmer et al. (2011b).

Yedoma is readily recognized where deep thermokarst lake basins are inset into thick ice-rich permafrost. In areas further south, within the modern boreal forest, Yedoma is obscured by forest cover. In general, the interior of Yukon and Alaska includes Yedoma deposits in areas of greater relief than their counterparts in Siberia, and Yedoma occurs further south into the present-day discontinuous permafrost zone (50–90% underlain by permafrost). In the Fairbanks and Klondike regions, where these deposits are best characterized, their distribution strongly reflects local site conditions. In these areas, Yedoma is found on north- and east-facing slopes and within narrow valleys along hillslopes.

Cryolithology

Yedoma sequences include buried cryosols marked by brownish horizons as well as the inclusion of organic matter and peat (Figures 5 and 6). Evidence of past cryoturbation, highlighted by the presence of the organic matter, is common. The poorly sorted clastic sediments range in grain size dominantly from silt to fine-grained sand and sometimes contain coarser-grained sand and gravel (Trask sorting 1.5–9, mean grain size 10–300 μm). Grain-size characteristics differ from site to site as well as within horizons, but modal grain size of nearly all samples is within the silt and fine sand range (Fraser and Burn, 1997; Sanborn et al., 2006). The presence of multimode grain-size distributions (Figure 8) suggests a range of transport processes and underscores the importance of redeposition of silts with coarser grain sizes. Heavy-mineral analyses of Siberian Yedoma suggest significant differences in detrital composition between sites, indicating different local sediment sources of the hinterland (Schirmer et al., 2011b).

Figure 9 Mineral sediment with ice bands and fine lens-like reticulate cryostructures and some brownish plant detritus-rich patches typical of Yedoma deposits from the Buor Khaya Peninsula, Laptev Sea. Photograph by J. Strauss, AWI Potsdam.

Cryogenic structures in Yedoma deposits, in particular, the presence of syngenetic ice wedges, are similar at most study sites. Ice wedges often have pronounced shoulders and partial thaw surfaces, indicating the episodic nature of sedimentation and permafrost aggradation with varying active-layer depth on the polygonal ground network (Figure 2). Thin horizontal ice lenses or net-like reticulated ice veins subdivided by up to 2–4-cm-thick ice bands are common (Figure 9); they indicate enrichment in segregated ice near the permafrost table under subaerial conditions, including inundated polygonal ponds, by a slowly aggrading soil surface, changing active-layer thickness, and freezing under poorly drained conditions (e.g., Romanovskii, 1977).

The frozen sediment sequences commonly contain excess ice, with gravimetric ice contents (ratio of the mass of liquid water and ice in a sample to the dry mass of the sample, expressed as a mass percentage, [van Everdingen, 1998](#)) of 70 to >100 wt% ([Schirmer et al., 2011b](#)); this corresponds to an ice content of 30 to more than 60 wt% for the sediment columns of Yedoma exposures. Considering that ice wedges

Figure 10 Graminoid-rich paleosol with roots overlying ice wedge, marking the paleoactive layer when the soil was formed. The paleosol is cross-cut by a syngenetic ice wedge (vertical arrow at left) and includes beds of Dominion Creek tephra (82 ± 9 ka; horizontal arrow), marking early MIS 4 cold conditions in Yukon. Ice axe is 80 cm long. Adapted from Froese et al. (2009).

account for about 50% by volume of most Yedoma sequences, the total volumetric ground ice content likely ranges from 65 to 90%.

Stable isotope signatures of ground ice ($\delta^{18}\text{O}$, δD , d-excess) are used as a proxy for winter paleotemperatures (the most negative $\delta^{18}\text{O}$ and δD values reflect the coldest temperatures) and moisture sources. Late Pleistocene ice-wedge ice reflects very cold winter temperatures and moisture sources that are isotopically distinct from Holocene values (e.g., [Meyer et al., 2002](#); [Vasil'chuk, 1992](#); [Wetterich et al., 2011](#)).

Total organic carbon (TOC) content in Yedoma deposits, based on more than 700 analyses from 14 Siberian sites, is variable (<1 to >20 wt%) and relatively high (site-specific averages from 1.2 to 4.8 wt%; [Schirmer et al., 2011a,b](#)). Woody macrofossils and peat are present, along with numerous small filamentous rootlets and dispersed organic detritus. Detailed studies of paleosols within Yedoma deposits indicate that much of the organic matter accreted as root detritus from graminoid vegetation under periglacial conditions ([Figure 10](#); [Sanborn et al., 2006](#)). Thaw unconformities truncating ice wedges, syngenetic ice wedges with pronounced shoulders ([Figure 2](#)), and cryoturbated paleosols, all record episodic changes in sedimentation and paleoactive-layer depths. The $\delta^{13}\text{C}$ values of bulk organic material range from about -29 to -24 ‰, indicating that only freshwater aquatic and subaerial terrestrial environments contributed this material to the formation of Yedoma deposits ([Schirmer et al., 2011b](#)). Variations in TOC content, C/N ratio, and $\delta^{13}\text{C}$ values ([Figure 11](#)) relate to changes in bioproductivity, intensity and character of cryosol formation, and different degrees of organic matter

Figure 11 Compilation of cryolithological parameters of the Yedoma sequence and the Holocene cover from Bykovsky Peninsula, Laptev Sea according to [Schirmer et al. \(2011b\)](#).

decomposition, as well as variations in plant associations. High TOC contents, high C/N ratios, and low $\delta^{13}\text{C}$ values reflect less-decomposed organic matter under anaerobic conditions, which were characteristic of the interstadial Marine Isotope Stage (MIS) 3. During cold stages, such as MIS 2, TOC was less variable and generally low, indicating more stable environments with reduced bioproductivity and low C/N ratios. High $\delta^{13}\text{C}$ values reflect relatively dry, aerobic conditions.

Fossils and Paleoenvironmental Archives

Yedoma deposits are among the most productive hosts for preserving Pleistocene fossils in the northern hemisphere (Guthrie, 1990), and because of the presence of permafrost, they provide exceptional preservation conditions, unequaled elsewhere (Shapiro and Cooper, 2003). Intense research over the past decades has already been undertaken to use the fossil record to describe past environments of Beringia through a combination of proxies such as pollen, soils, plant macrofossils, insects, mammals, ostracods, or testate amoebae for quantitative and qualitative reconstructions (e.g., Sher et al., 2005; Wetterich et al., 2008; Zazula et al., 2007).

Across Alaska, Yukon, and Siberia, the mammoth fauna remains preserved in Yedoma are dominated by mammoth (*Mammuthus primigenius*), horse (*Equus caballus*), bison (*Bison priscus*), and caribou (*Rangifer tarandus*). Fossils of less common species are recovered occasionally, including camel (*Camelops hesternus*), musk ox (*Ovibos pallantis*), woolly rhino (*Coelodonta antiquitatis*), and saiga antelope (*Saiga* sp.). Carnivores such as cave lion (*Panthera leo spelaea*), short-faced bear (*Arctodus simus*), and wolf (*Canis lupus*) are also rare. Some of these species occurred only on one side of the Bering Land Bridge (such as the wholly rhino in Siberia, and camel and short-faced bear in eastern Beringia), while others were widely distributed across Beringia. The grazing fauna, much of it collected from detrital fossils recovered from Yedoma exposures across Beringia, have been linked to late Pleistocene environments of the region through radiocarbon dating (e.g., Sher et al., 2005). Mummified or freeze-dried carcasses recovered from these sites, although rare, highlight the role of permafrost in preserving the late Pleistocene paleontological record (Guthrie, 1990; Shapiro and Cooper, 2003).

Paleobotanical materials are equally well preserved within Yedoma and, in particular, have become better understood through plant macrofossils recovered from these deposits. For example, in eastern Beringia, plant macrofossils from Arctic ground squirrel (*Spermophilus parryii*) nests, seed caches, and burrows are dominated by grasses, dryland sedges, sage, and a wide variety of flowering forbs (e.g., Zazula et al., 2007). Together, these plants indicate open grass- and forb-rich steppe tundra in eastern Beringia, developed on largely well-drained substrates during MIS 2 (Froese et al., 2009).

Palynological analyses from the Yedoma indicate a dominance of herbs (e.g., *Artemisia*, Caryophyllaceae, Asteraceae), grasses (e.g., Poaceae, Cyperaceae), and to a lesser extent, dwarf shrubs (e.g., *Salix*, *Alnus*, *Betula*). According to Andreev et al. (2011), the period of Yedoma formation in Siberia was characterized by sparse grass-sedge tundra growing in an extremely cold and dry climate during MIS 4, tundra-steppe

vegetation with higher productivity in a more moderate and humid climate during MIS 3, and sparse grass-tundra present in the cooler and drier climate of MIS 2. Nevertheless, the presence of algal spores and remains of other aquatic organisms (e.g., hydrophytes, ostracods) found in many samples indicates the existence of small freshwater ponds in low-center polygons. In addition, spores from dung-inhabiting fungi indicate the widespread occurrence of mammoth fauna species during the time of Yedoma formation (Sher et al., 2005). Floral and faunal communities that existed when Yedoma formed disappeared approximately at the Pleistocene–Holocene transition. The paleoecosystem associated with Yedoma, often called Mammoth Steppe or steppe tundra in eastern Beringia (e.g., Guthrie, 1990) or Tundra-Steppe in western Beringia (e.g., Yurtsev, 1982), combined elements found in both cold tundra and dry steppe environments. The climate was more continental in the late Pleistocene Arctic than today, and reconstructions from Siberia indicate colder winters and warmer summers, suggesting stronger seasonal gradients in temperature and precipitation (e.g., Andreev et al., 2011). Because of the polygonal patterned ground relief, the tundra-steppe landscape was characterized by a patchwork-like distribution of vegetation communities at a local scale.

Formation Processes

Yedoma in Northeast Siberia (Western Beringia)

The processes that formed Yedoma in western Beringia are disputed, and some differences of interpretation remain between researchers of western and eastern Beringia. These differences largely reflect the prominence attributed to eolian processes, and in particular, the interpretation of the silts as being primarily loess by researchers in Yukon and Alaska. In contrast, workers in Siberia have, in recent decades, proposed several hypotheses about the origin of Yedoma, including alluvial, glaciolacustrine, deltaic, proluvial and colluvial, cryogenic-eolian, nival, and polygenetic processes (for an overview, see Schirmer et al., 2011b). Zhestkova (1982) and Sher (1997) proposed a polygenetic origin in which Yedoma deposits accumulated under different sedimentation regimes, but were largely controlled by similar landscape and relief characteristics, climate conditions, periglacial processes, and sediment sources. An overarching similarity is the presence of large syngenetic ice wedges and remains of the late Pleistocene mammoth fauna and tundra-steppe flora.

A broad concept of Yedoma formation that combines processes of cryogenic weathering, material transport and accumulation, and relief shaping under cold-arid climate conditions was proposed by Kunitsky et al. (2002). According to this cryolithogenetic concept (cryolithogenesis: formation of sedimentary materials in the permafrost regions, according to Yershov, 2004), Yedoma represents a characteristic periglacial facies whose formation is controlled by the interaction of several climatic, landscape, and geological preconditions typical for nonglaciated Arctic lowlands (Figure 12). Initially, mixtures of windblown snow, plant, and fine-grained mineral detritus accumulated in numerous perennial snow fields that were topographically protected not only among hills and low mountain ranges, but also on terrain edges (e.g., steep slopes,

Figure 12 Landscape characteristics and development stages (a–d) during late Pleistocene Yedoma formation in Siberian Arctic lowlands (according to Schirrmeister et al. (2011b)). The arrows in part d indicate the various types of sediment transport described in the text (e.g., alluvial, proluvial, colluvial, eolian).

valleys, and cryoplanation terraces; Figure 12(a)). Around their margins and beneath the snowfields, intense freeze-thaw cycles associated with wet conditions (frost weathering) formed additional fine-grained sediment (Figure 12(b); Konishchev and Rogov, 1993; Kunitsky et al., 2002). Some of this sediment and associated organic matter was transported downslope by runoff from seasonal meltwater (Figure 12(c)). This fine-grained detritus was then transported further by a variety of processes (alluvial, proluvial, colluvial, slope wash, solifluction, permafrost creep, and eolian) to foreland plains, cryopediments, or large alluvial fans. As a result, different types of Yedoma deposits accumulated, with variable grain-size distributions, dependent on local environmental conditions. As sediment aggraded in flat accumulation areas, polygonal ice-wedge systems developed syngenetically (Figure 12(d)). Over thousands of years, these recurrent processes of snowfield accumulation, snow melt, and meltwater transport and secondary sediment transport processes led to the accumulation of thick Yedoma deposits on wide plains. On a smaller scale, similar phenomena can be observed today on numerous slopes and terrain steps in northeastern Siberia, where nivation is an essential geomorphological factor (Kunitsky et al., 2002).

The typical Ice Complex formation therefore consisted of several concurrent cryogenic processes, including sediment accumulation and freezing, ice segregation, syngenetic ice-wedge growth, sediment reworking, peat aggradation, cryosol formation, and cryoturbation, all promoted by enduring and harsh continental climate conditions. The formation of large polygonal systems of ice wedges and thick continuous sequences of frozen deposits recorded the persistence of accumulation areas that were stable and poorly drained, and had low topographic gradients. In short, the proposed cryolithogenic model integrates several previous concepts and emphasizes the polygenetic character of Yedoma deposits. It also identifies several sediment sources, weathering processes, and pathways by which sediments in typical periglacial landscapes can build up such fine-grained ice-rich deposits under extreme cold-climate conditions.

In Siberia, Yedoma deposits predominantly date from MIS 3 and 2. The initiation of Yedoma formation, based on radiocarbon dates, varies between about >55 ka BP on the New Siberian Islands and 27 ka BP at the western Laptev Sea coast. The latest deposition is dated between 28 ka BP on the New Siberian Islands and 17–13 ka BP in the western Laptev Sea. Unconformities within Yedoma sequences are common, encompassing up to 20 ka, and likely record thermokarst and thermoerosion processes. In general, the basal layers of Yedoma contrast sharply with the underlying deposits – often fluvial sands with peat layers, or loess-like flood plain deposits – dated by $^{230}\text{Th}/^{234}\text{U}$ and luminescence to an age of 100–60 ka (Schirrmeister et al., 2011b). The upper boundary of Yedoma is characterized by a thaw unconformity and separates locally confined Holocene deposits on top of Yedoma hills.

Alaska and Yukon ‘Muck’: Eastern Beringia Equivalents of Yedoma

As in Siberia, early work in northwestern North America was controversial, and workers argued that the silts, or later ‘muck’ deposits, in Alaska and Yukon may have been produced by

lacustrine, estuarine, eolian, residual weathering or fluvial processes, or their interaction (e.g., [Taber, 1943](#)). Following work by [Péwé \(1955\)](#), who argued strongly for an eolian origin, all workers have accepted a predominantly eolian origin for these sediments. In fact, no other ideas have been seriously entertained since the late 1950s. This likely reflects differences in the overall setting of these deposits, and perhaps a more generous consideration of loess in the North American literature relative to the concept of Yedoma in Siberia.

Loess is the most widely distributed surficial material in the nonglaciated areas of Alaska and Yukon ([Péwé, 1975](#)). Many of the areas with Yedoma in North America are associated with uplands and valleys, and to a lesser degree with extensive accumulation plains similar to the North Siberian shelves, resulting in the common differentiation into 'upland silt' and valley-bottom 'muck' deposits. These differences have been important in the development of ideas concerning the genesis of these deposits. Upland silts mantle hilltop exposures and are commonly found on alluvial terraces or sheltered behind bedrock obstacles, and have been unambiguously interpreted as loess ([Muhs et al., 2008](#); [Péwé, 1975](#)). However, it should be noted that these upland silt deposits are not ice-rich and differ significantly from Yedoma deposits as described in valley-bottom settings (e.g., [Bray et al., 2006](#); [Froese et al., 2009](#); [Péwé, 1975](#)).

In Péwé's original work and that of earlier researchers, the valley-bottom 'muck' deposits were considered to be 'reworked loess' derived from mixing of upland silts with organic material, accumulated syngenetically with permafrost growth in valley-bottom settings, and interbedded with primary airfall-derived loess. At some sites, well-developed bedding and sandy lenses indicate fluvial influence during deposition, but these beds are relatively minor at most sites. Commonly, the loess-adjective 'loessal' is used to describe material dominated by coarse silt and fine sand grain sizes, much of which is likely primary airfall loess, though evidence of secondary, short-distance redeposition by snowmelt or sheet flows may also be present (e.g., [Froese et al., 2009](#); [Sanborn et al., 2006](#)). Loess from MIS 2 is relatively thin on upland sites ([Muhs et al., 2008](#)), whereas thick accumulations dating to that time are present in valley-bottom sites ([Guthrie, 1990](#); [Péwé et al., 1975](#)). This suggests that either the sediments accumulated thickly in valley bottoms or these valleys acted as sediment traps, while upland surfaces, with sparse vegetation cover and, thus, low friction, may have been bypassed by these sediments (cf. [Muhs et al., 2008](#)).

The degree of mixing of the valley-bottom 'muck' deposits has been an open question, and throughout the 1970s and 1980s likely discouraged much paleoenvironmental work on these sites. However, increasingly large numbers of radiocarbon ages, typically on plant macrofossils, show few inversions in sedimentary sequences and argue for the stratigraphic coherence of these archives and their suitability for paleoenvironmental reconstruction ([Froese et al., 2009](#); [Zazula et al., 2007](#)).

A detailed study of paleosols within Yedoma deposits in the Klondike area, correlated between sites by distinctive distal tephras dating to MIS 2 and 4, confirms a consistent record of sedimentation, with syngenetic permafrost aggradation interrupted by periods of soil development between sites in valleys 20 km apart ([Sanborn et al., 2006](#)). These authors

showed that the valley-bottom silts underwent only limited weathering. Micromorphological evidence from the soils indicated that the organic matter within the sediments, primarily fine graminoid detritus, accreted mainly by below-ground inputs of root detritus as the surface sediments aggraded with loessal inputs ([Sanborn et al., 2006](#)). Importantly, the correlation of these consistent soil properties and timing of loess and syngenetic permafrost aggradation argue for regional controls on sedimentation rather than local site conditions.

In eastern Beringia, Yedoma formation largely dates to the late Pleistocene. [Péwé \(1975\)](#) argued for a consistent climatically driven period of ice-rich loessal sedimentation, which he named the Goldstream Formation. This formation postdated a significant thaw of permafrost during the last interglacial (MIS 5e) and likely dates through the Wisconsin. Subsequent workers have dropped the formal definition, but based on radiocarbon ages and tephrochronology, most of the Yedoma deposits date to late MIS 3 and MIS 2. Radiocarbon ages are fairly consistent between interior Yukon and Alaska for a major period of Yedoma development during MIS 2, beginning around 30 ka BP and continuing until ca. 11.5 ka BP ([Fraser and Burn, 1997](#); [Hamilton et al., 1988](#); [Zazula et al., 2007](#)). A pronounced unconformity at ca. 10 ka BP marks the degradation of these surfaces and is characterized by organic-detritus-rich sedimentation above the thaw unconformity sediments ([Fraser and Burn, 1997](#)). Earlier Yedoma sedimentation during MIS 4 is well documented in central Yukon through the presence of the Sheep Creek-K tephra (ca. 80 ka; [Froese et al., 2009](#)). At each time slice where these deposits are recognized, and paleoenvironmental reconstructions are available, the reconstructions indicate the aggradation of the loessal silts in an open, grass- and forb-rich steppe-tundra community, suggesting that these deposits are a recurrent feature of cold stages during the Pleistocene of Beringia ([Froese et al., 2009](#)).

In Alaska, more recent studies of Yedoma deposits have focused on the well-known CRREL permafrost tunnel near Fairbanks that exposed fine-grained frozen sequences containing syngenetic ice wedges ([Bray et al., 2006](#); [Hamilton et al., 1988](#); [Kanevskiy et al., 2008](#); [Shur et al., 2004](#)). A Yedoma site with very similar characteristics to Northeast Siberian sites is reported from the Itkillik River in the Arctic Foothills ([Kanevskiy et al., 2011](#)). These Yedoma deposits cover the period between >48 and 14.3 ka BP.

Conclusion

During the late Pleistocene cold stages in Beringia, Yedoma deposition was favored by a cold, dry climate that precluded widespread glaciation of lowlands and low mountain ranges, and resulted in intense periglacial weathering, sediment transport, accumulation, and syngenetic permafrost growth for several tens of thousands of years. The overall characteristics of Yedoma in Siberia (West Beringia) and North America (East Beringia) are given in [Table 1](#). The formation of large polygonal ice-wedge systems and sequences of ice-rich silty deposits tens of meters thick was closely related to the persistence of stable, poorly drained, and flat to gently sloping accumulation areas in the lowlands of Siberia and northern Alaska. Within the interior of Yukon and Alaska, Yedoma deposits are more

Table 1 Typical features of the Yedoma deposits

	<i>West Beringia (Siberia)</i>	<i>East Beringia (Alaska and Yukon)</i>
Formation age	80–12 ka BP	
Stratigraphy	MIS 4–MIS 2	
Terminology	Ice Complex, Yedoma Suite	'Muck' deposits or syngenetic late Pleistocene perennially frozen ice-rich silts
Landscape	Stable, poorly drained areas with low topographic gradient	
Distribution	East Siberian Arctic lowlands and large river valleys, foothills	Foothills and lowlands in northern Alaska; north easterly exposures and within narrow valleys in interior Yukon and Alaska
Sediment	Poorly sorted, organic-rich silt and silty sand	Organic-rich silt and silty sand; largely related to eolian sedimentation
Ground ice	Ice saturated or supersaturated, syngenetic ice wedges, segregation ice	
Paleoclimate	Highly continental, cold arid	
Paleoecology	Tundra steppe/Mammoth steppe, cryoxeric vegetation, Mammoth Fauna	
Genesis	Syngenetic permafrost of multiple origins depending on region: nival, alluvial, proluvial–colluvial, sheet flow, soil creep, or eolian sedimentation	Largely eolian sedimentation (airfall loess) with syngenetic permafrost, but locally, other deposits may be interbedded

variable, reflecting the variation of local site conditions with topography. Paleontological reconstructions of the environment during Yedoma formation indicate the presence of cryoxeric steppe-tundra communities. Yedoma deposits are defined by distinct cryolithological and sedimentological characteristics, and are preserved today in elevated erosional remnants in thermokarst landscapes termed Yedoma hills in Siberia, while in the previously unglaciated region of Alaska and the Yukon Territory, these deposits are found mostly in foothill regions, on north-facing slopes, and as fill in narrow valleys. In summary, Yedoma must be considered as a special type of periglacial or cryogenic facies typical of cold stages of late Pleistocene Beringia.

Paraglacial Geomorphology

C K Ballantyne, University of St. Andrews, St. Andrews, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction and Definition

Paraglacial geomorphology is the study of the ways in which glaciated landscapes adjust to nonglacial conditions during and after deglaciation. The term paraglacial was introduced by Ryder (1971) to describe 'nonglacial processes that are directly conditioned by glaciation' (Church and Ryder, 1972), but it has subsequently been adopted to describe glacially conditioned landforms, landscapes, and sediment accumulations, as well as processes. This widened usage has prompted redefinition of the term as a descriptor of 'nonglacial earth-surface processes, sediment accumulations, landforms, land systems, and landscapes that are directly conditioned by glaciation and deglaciation' (Ballantyne, 2002a). Initial research on paraglacial geomorphology focused on fluvial responses to late Pleistocene or early Holocene deglaciation. The past two decades, however, have seen an upsurge in research on paraglacial landscape adjustment following recent glacier retreat, together with a wider focus that incorporates rock slopes, drift-mantled slopes and glacier forelands, alluvial and lacustrine systems, and glaciated coasts. Developments in paraglacial geomorphology before 2001 are reviewed in Ballantyne (2002a). A remarkably large body of pertinent literature has appeared since then, largely devoted to landscape changes following recent (post-Little Ice Age) deglaciation.

Theory

The Paraglacial Sediment Cascade

The retreat of glacier ice often reveals landscapes in an unstable or metastable state, and in particular, results in the exposure of glaciogenic or glacially conditioned sediment sources that are subsequently released and reworked by a variety of processes over a wide range of timescales. Rock masses stressed by the weight of glacier ice experience decompression, opening of joints, and adjustment in the form of rockfalls, rock topples, rock slides, rock avalanches and gravitational slope deformation. Glaciogenic sediments on valley-side slopes may be reworked by translational landslips, debris flows, snow avalanches, and running water. Valley-floor glaciogenic sediments (till, glaciofluvial deposits, and glacial-lacustrine sediments) are eroded, transported, and redeposited by rivers, forming alluvial fans and valley fills, or deltas or bottom deposits in lakes and fjords. Glaciofluvial deposits exposed at the coast are eroded by waves and currents, and redeposited as barrier deposits and shelf sediments.

The paraglacial system may thus be envisaged as a sediment cascade in which nonrenewable sediment sources (unstable rockwalls, drift-mantled slopes, valley-floor glaciogenic deposits, and coastal glaciogenic deposits) are released or entrained by a range of processes and transported toward terminal sediment sinks (Figure 1). Source-to-sink transport is often interrupted,

however, by sediment redeposition in paraglacial sediment stores such as talus accumulations, debris cones, alluvial fans and valley fills, deltas, beaches, spits, and bars. Some paraglacial sediment stores continue to accumulate for several millennia, but others experience degradation within a few centuries or millennia of formation.

Models of Paraglacial Sediment Yield

Ballantyne (2002b) has argued that for primary paraglacial systems in which sediment sources are not replenished, the trajectory of sediment reworking may be approximated by an exhaustion model in which the rate of sediment yield is related to the remaining available sediment by a negative exponential function:

$$S_t = S_0 e^{-\lambda t} \quad [1]$$

where t is time elapsed since deglaciation, S_t the proportion of sediment available for reworking at time t , S_0 the sediment available for reworking at $t=0$, and λ is the rate of sediment loss by release and/or stabilization (Figure 2(a)). The value of λ varies over several orders of magnitude for particular paraglacial systems. On glacier forelands and drift-mantled slopes, for example, most landform adjustment and associated sediment reworking is completed within a few decades or centuries, whereas rock-mass adjustment to glacial unloading may continue to affect slope stability for many millennia after deglaciation (Figure 2(b)).

Secondary paraglacial systems (primarily fluvial systems), in which sediment inputs include both glaciogenic sediment sources and remobilization of upstream paraglacial sediment stores, behave in a more complex way. Church and Slaymaker (1989) interpreted a downstream increase in the specific non-dissolved sediment yield of rivers draining deglaciated terrain as indicating a delayed peak in paraglacial sediment yield in large catchments, an argument developed further by Church (2002), who envisaged a 'wave' of reworked sediment progressing down the fluvial system over millennial timescales. Alternatively, a downstream increase in specific sediment yield may be consistent with the simple exhaustion model, providing (1) that initial sediment availability (S_0) is greater in small tributary basins and (2) that the rate of decline in sediment supply (λ) is more gradual with increasing catchment size (Figure 2c). The latter assumption is likely to be met in most cases because of the contribution of reworked sediment from upstream sources, but the validity of the former assumption probably varies from site to site.

The models illustrated in Figure 2(a)–2(c) assume steady-state conditions in which there is no change in process-generating mechanisms or other boundary conditions. Over millennial timescales, this is rarely, if ever, the case, and paraglacial sediment flux may be influenced by such factors as climate change (advance or retreat of glaciers, changes in

Figure 1 Paraglacial sediment cascade. Sediment may enter storage several times during source-to-sink transport. Reprinted from Ballantyne CK (2002) Paraglacial geomorphology. *Quaternary Science Reviews* 21: 1935–2017, © 2002, with permission from Elsevier.

catchment hydrology or in the magnitude and frequency of extreme rainstorm events), tectonic activity (uplift, tilting, or seismic events), sea-level change, or anthropogenic influences such as vegetation burning, deforestation, or cultivation. Such extrinsic perturbations tend to prolong, rejuvenate, or reinitiate paraglacial sediment reworking (Figure 2(d)). Lowering of base level by glacioisostatic uplift or deglaciation, for example, may cause renewed incision and reworking of glaciogenic deposits, paraglacial fans, and valley fills (e.g., Meigs et al., 2006), and glacioeustatic sea-level rise permits rising seas to tap pristine sources of littoral glaciogenic sediment, rejuvenating nearshore paraglacial sediment flux (Forbes and Syvitski, 1994). Extreme climatic events such as exceptional rainstorms may cause reworking of valley-side drift deposits by debris flows and torrents several millennia after the initial phase of paraglacial sediment reworking has ended.

Modeling Paraglacial Sediment Storage

As paraglacial sediment stores such as talus cones, debris cones, alluvial fans, and alluvial valley fills accumulate, they are subject to erosional losses. If it is assumed that rates of non-dissolved sediment loss from paraglacial sediment stores are related to sediment availability (i.e., the volume of erodible sediment in the sediment store), then the volume of sediment in storage (S) at time t is approximated by

$$S = (S_0 - S_0 e^{-\lambda t}) e^{-\kappa t} \quad [2]$$

where κ is the rate of sediment loss from the store. If S_0 is set at unity, this simplifies to

$$S = (1 - e^{-\lambda t}) e^{-\kappa t} \quad [3]$$

Figure 3 illustrates the change in sediment storage for $\lambda = 1.0 \text{ ka}^{-1}$ and a range of values of κ . One implication of

Figure 2 Models of paraglacial sediment flux. (a) Simple exhaustion model of paraglacial sediment release, in which rate of release (λ) is related to the proportion of 'available' sediment remaining. (b) Illustrative exhaustion curves for different primary paraglacial processes: (1) rock-slope failure, (2) rockfall and talus accumulation, (3) accumulation of large alluvial fans, (4) deep-seated gravitational slope deformation, (5) modification of drift-mantled slopes, and (6) modification of glacier forelands. (c) Exhaustion model of paraglacial sediment release for drainage basins of different size. (d) Influence of external perturbation on the temporal pattern of paraglacial sediment release: effect of base-level change of sediment release in fluvial systems. Reproduced from Ballantyne CK (2003) Paraglacial landform succession and sediment storage in deglaciated mountain valleys: Theory and approaches to calibration. *Zeitschrift für Geomorphologie Supplementband* 132: 1–18.

Figure 3 General model of paraglacial sediment storage. Sediment stores such as debris cones, alluvial fans, or valley fills experience an initial period of net accumulation, succeeded by a longer period of net sediment loss. This occurs because the sediment sources feeding such sediment stores are nonrenewable. Reproduced from Ballantyne CK (2003) Paraglacial landform succession and sediment storage in deglaciated mountain valleys: Theory and approaches to calibration. *Zeitschrift für Geomorphologie Supplementband* 132: 1–18.

this model is that for all paraglacial sediment stores that experience output losses ($\kappa > 0$), an eventual change from net sediment accumulation to net sediment loss is an intrinsic property of paraglacial sediment storage; this reflects the nonrenewable nature of paraglacial sediment sources. Another implication is that both the maximum amount of sediment in storage ($\max(S)$) and the timing of maximum sediment storage (t') are related to the relative values of λ and κ , and can be expressed as

$$\max(S) = \left[\frac{\lambda}{\lambda + \kappa} \right] \left[\frac{\kappa}{\lambda + \kappa} \right]^{\kappa/\lambda} \quad [4]$$

and

$$t' = -\ln \frac{[\kappa/(\lambda + \kappa)]}{\kappa} \quad [5]$$

These relationships potentially allow the history of net sediment accumulation and loss to be retrodicted for individual paraglacial sediment stores, provided that time since deglaciation and time of maximum sediment storage are known, and both the maximum and present volumes of stored sediment can be evaluated (Ballantyne, 2003). On short (decadal and centennial) timescales, however, the exhaustion model outlined earlier may be delayed by sediment accumulating behind moraine barriers (Cossart and Fort, 2008), and over long timescales, fluvial response is likely to be complicated by the fact that sediments of different sizes move at different rates through the fluvial system (Church, 2002).

Paraglacial Succession

Because paraglacial subsystems relax over widely differing timescales (Figure 2(b)), some paraglacial sediment stores experience net erosion and degradation even as others continue to accumulate. In consequence, paraglacial landform assemblages are increasingly dominated by sediment stores with the greatest formative longevity and persistence in the landscape (Figure 4). This evolutionary process is termed paraglacial succession (Ballantyne, 2003). Owen et al. (1995) have illustrated this concept by mapping the paraglacial landforms occupying valleys deglaciated at different times in the Lahul Himalaya, showing that these exhibit a marked increase through time in areas occupied by alluvial fills, alluvial fans, and slopes modified by mass movement.

Paraglacial Land Systems

Ballantyne (2002a) has identified six paraglacial land systems characterizing particular geomorphological contexts: rock slopes, drift-mantled slopes, glacier forelands, alluvial settings, lacustrine deposits, and coastal areas. It is important to appreciate, however, that these frequently overlap spatially. Deglaciated mountain valleys, for example, may incorporate rock-slope failures, reworked drift slopes, and paraglacially modified glacier forelands and alluvial fans, and lacustrine and coastal responses are strongly linked to the passage of reworked glaciogenic sediment through the fluvial system.

Rock Slopes

Glaciation and deglaciation affect rock-slope stability in two ways. First, glacial erosion tends to steepen and lengthen rock slopes, increasing and reorientating the self-weight stresses acting behind the rock face. Second, during glacial episodes, the weight of overlying or adjacent glacier ice increases stresses within rock masses. As some of the resulting rock deformation is elastic and stored within the rock as strain energy, deglaciation results in gradual rock-mass dilation, often termed stress release. This process causes propagation of the internal joint network, together with reduced cohesion along joints and reduction of internal locking stresses. These changes may initiate three types of responses on steep rockwalls, namely, catastrophic rock-slope failure, deep-seated gravitational rock-mass deformation, and slow recovery of equilibrium through episodic rockfalls. On lower slopes and valley floors, stress release is manifest in the development of decompression structures (stress-release joints) on erosional bedforms such as roches moutonnées (Cossart et al., 2008). The nature of rockwall response is determined mainly by joint density, and orientation and inclination of the principal joint sets relative to rock faces.

Catastrophic rock-slope failure

There are numerous documented examples of catastrophic rock-slope failures on recently deglaciated terrain (Ballantyne, 2002a). These have generally been attributed to debuttressing of glacially steepened rockwalls during deglaciation and associated stress release, though in some cases, permafrost degradation and thaw of ice in joints may also have contributed to the failure. There is also evidence for widespread paraglacial rock-slope failure following late Pleistocene deglaciation (e.g., Ballantyne et al., 2009). Cossart et al. (2008) have demonstrated that major rockfalls and rock avalanches in the Upper Durance catchment (French Alps) are concentrated in lower valley-side slopes within the limits of glacial occupancy at the Last Glacial Maximum, and that their locations coincide with areas of inferred high glacial loading stress, consistent with the interpretation of these rock-slope failures as a response to deglacial stress release.

Cruden and Hu (1993) proposed that the pattern of paraglacial rock-slope failure might be approximated by an exhaustion model (Figure 2(a)). Their model assumes that there are a finite number of potential failure sites following deglaciation, that each site fails only once, and that the probability of individual failures remains constant. The overall probability of failure within a given area therefore declines exponentially with time as the number of potential failure sites diminishes. Although this model has not been rigorously tested, cosmogenic isotope exposure dating of rock-slope failures in formerly glaciated mountain environments is consistent with a general pattern of frequent failures during or soon after deglaciation followed by less frequent failures thereafter, the latter probably conditioned by rock-mass weakening due to stress release but triggered by earthquakes or extreme rainstorms (Ballantyne et al., 2009; Cossart et al., 2008; Figure 5).

Deep-seated gravitational slope deformations

Deep-seated gravitational slope deformations (rock-mass deformations) are widespread on steep slopes in formerly

Figure 4 Paraglacial succession (schematic). (a) After deglaciation, glacial landforms and sediments are largely intact. (b) After a few millennia, alluvial fans and valley fills approach their maximum dimensions, though paraglacial debris cones are already degraded; talus continues to accumulate and the delta has prograded into the lake. (c) After ~10–15 ka, little evidence of glacial deposition remains, paraglacial debris cones are reduced to eroded bluffs, paraglacial fans and valley fills have been entrenched, erosion of talus has commenced, and only the delta has a net positive sediment budget and continues to prograde. Reproduced from Ballantyne CK (2003) Paraglacial landform succession and sediment storage in deglaciated mountain valleys: Theory and approaches to calibration. *Zeitschrift für Geomorphologie Supplementband* 132: 1–18.

glaciated mountains and have been widely attributed to glacial steepening, debuttreasing, decompression, and paraglacial stress release. Such deformation often involves downslope displacement of entire mountainside slopes, sometimes covering areas over 1 km² in area, but usually without debris runoff. Landforms associated with rock-slope deformation include ridge-top graben (trenches), tension cracks, minor rock top-ple, anticarps, and bulging slopes (Figure 6). Recent downwastage of the Affliction Glacier in British Columbia, for example, has resulted in slow gravitational displacement of roughly 30 million cubic meters of rock with surface strain rates of a few millimeters to a few centimeters per year, and associated development of tension cracks, anticarps, graben, and collapse pits (Bovis, 1990; Figure 7). The widespread nature of similar features on mountains that now lack glacier

ice suggests that paraglacial rock-slope deformation commonly accompanied late Pleistocene deglaciation, but dating control is weak and it is not established whether deformation typically occurred as a single rapid event, a series of intermittent shifts, or gradually through rock-mass creep. The nature of failure is also unclear in most cases: this may have occurred along a continuous shear surface, or over two or more shear planes separated by zones of fractured rock, or over a deep-seated zone of crushed rock.

Paraglacial rockfall and talus accumulation

Another response of glacially steepened rockwalls to deglaciation is pronounced rockfall activity and consequent accumulation of talus. Several authors have noted that recent rockfall rates are inadequate to account for the large volumes of talus

below rockwalls deglaciated at the end of the Pleistocene, and have suggested that rockfall was enhanced by stress release immediately after deglaciation (Ballantyne, 2002a). Curry and Morris (2004), for example, calculated that 84% of rock-wall retreat due to rockfall at a site in south Wales occurred between 17.3 cal ka BP and 11.5 ka BP following late Pleistocene deglaciation, and estimated that roughly 50% of rockfall occurred within 1000 years after deglaciation. Rapid talus accumulation following recent glacier retreat has also been observed in a range of mountain environments. Frequent rock-falls following late Pleistocene deglaciation were probably instrumental in the development of now-relict talus rock glaciers in former permafrost areas.

Drift-Mantled Slopes

Glacier retreat often leaves lower valley-side slopes mantled in thick glaciogenic deposits, sometimes composed of stacked lateral moraines. Such deposits are vulnerable to erosion by shallow translational failure, debris flow, snow avalanches, streamflow, and surface wash. In extreme cases, these processes completely rework drift-mantled slopes, forming a land system of deep gullies, intervening drift arêtes, coalescing debris cones, and slope-foot fans (Figure 8). In the Himalayas, this landform association achieves spectacular dimensions (Iturrizaga, 2008; Owen et al., 1995), and in high-latitude environments, gully-ing of valley-side glaciogenic sediments may be triggered by rapid melt of buried dead-ice cores (Mercier et al., 2009). In mountain environments where recent ice downwastage has exposed steep-sided lateral moraines, proximal moraine slopes may be extensively modified by slumping and debris falls, with rapid evacuation of debris by recurrent debris flows (Curry et al., 2006). Rates of gully erosion can be very rapid. On recently deglaciated terrain in the Jostedal area in Norway, Ballantyne and Benn (1994) calculated a minimum incision rate of 50–100 mm year⁻¹ for gullies excavated on valley-side drift deposits between AD 1943 and AD 1991, and Curry et al. (2006) inferred average minimum incision rates of ~95 mm year⁻¹ for gullies cutting into a lateral moraine in the Swiss Alps. In both cases, gullies appear to have reached

Figure 8 Paraglacial modification of drift-mantled slopes, Fåbergstølsdalen, Norway. Less than 50 years after glacier retreat, erosion by debris flows has removed most of the original valley-side drift deposits (stacked lateral moraines), creating deep unstable gullies and depositing coalescing debris cones at the slope foot.

their maximum dimensions within about 50 years after deglaciation, after which gully relief has been reduced by reduction of intergully slopes and gully infilling. Although complete transformation of drift-mantled slopes may be achieved within a few decades or centuries (Ballantyne and Benn, 1994; Curry et al., 2006; Mercier et al., 2009), renewed sediment remobilization long after the initial period of paraglacial modification sometimes occurs, usually in response to extreme rainstorm events. Degraded vegetation-covered gully systems and associated inactive debris cones are common in steep-sided valleys that were deglaciated at the end of the Pleistocene, and the aforementioned evidence suggests that many of these formed and atrophied within a century or two of ice-margin retreat.

Glacier Forelands

Valley-floor deposits exposed by glacier retreat tend to experience rapid modification by mass movement, frost sorting, wind erosion, and surface runoff. The slopes of steep-sided moraines decline to stable gradients within a few decades through slumping, and solifluction sometimes modifies the original form and near-surface structure of sediment bedforms (Ballantyne, 2002a). Recently deglaciated forelands often exhibit periglacial microforms, including sorted nets and stripes, boulder-cored frost boils, surface cracks, miniature solifluction lobes, and ploughing boulders, all of which imply disruption by freeze–thaw of near-surface glaciogenic deposits (Matthews et al., 1998). Deflation of unvegetated glaciogenic sediments by down-glacier katabatic winds causes loss of surface fines, and development of a surficial stony lag deposit, with associated accumulation of aeolian sands and silty sands farther downwind. During the retreat of Pleistocene ice sheets, wind erosion operated on a vast scale across outwash plains, resulting in the deposition of thick proximal coversands and distal loess accumulations of essentially paraglacial origin. Finally, the sediment load of proglacial meltwater streams is often substantially enriched by the addition of remobilized foreland sediments, mainly through surface wash, bank collapse, and sediment contributions from debris flows and slopewash from adjacent slopes. Though such effects may be comparatively short-lived due to sediment exhaustion and surface armoring (Orwin and Smart, 2004), elevated rates of sediment input into distal proglacial lakes often accompanies glacier retreat, raising the question of whether mineral-rich layers in the bottom sediments of such lakes represent episodes of glacier advance (as is often assumed) or sediment-enhanced proglacial runoff during glacier retreat (Ballantyne, 2002a). The main effects of paraglacial adjustment of recently deglaciated terrain are thus sediment redistribution, relief modification, and changes in near-surface sediment characteristics. Most modification is complete within a few decades or centuries due to stabilization of foreland sediments by vegetation, though sharp-crested moraines may experience progressive degradation over longer timescales.

Alluvial Land Systems

Paraglacial fans

Among the most widespread paraglacial landforms are debris cones and alluvial fans composed mainly of glaciogenic sediment reworked by debris flows and tributary streams.

Figure 9 Landforms and surficial sediments of the Gilgit Valley, Karakoram Mountains. The surface of the valley fill is dominated by huge paraglacial fans. Adapted from Owen LA (1989) Terraces, uplift and climate in the Karakoram Mountains, northern Pakistan: Karakoram intermontane basin evolution. *Zeitschrift für Geomorphologie Supplementband* 76: 117–146.

On recently deglaciated terrain, small debris cones and alluvial fans have accumulated and then degraded (due to depleted sediment input) within a few centuries (Ballantyne, 2002a). Large relict fans that accumulated following late Pleistocene deglaciation, however, often took several millennia to achieve their maximum dimensions before experiencing net erosion. Ryder (1971), for example, demonstrated that relict alluvial fans in British Columbia began to accumulate soon after deglaciation and continued to aggrade until shortly after ~ 6.6 ^{14}C ka BP. These fans were subsequently eroded by fan-head trenching due to reduction in sediment input, or incised due to base-level lowering, resulting locally in the formation of nested multilevel fans. The lithofacies of paraglacial fans are often complex, incorporating alluvial gravels, diamictic sediments deposited by debris flows and hyperconcentrated flows, and sometimes sediments of aeolian

and lacustrine origin. Some have impressive dimensions: the lower Cheekye fan in British Columbia, for example, occupies 8.3 km^2 . Roughly 1.4 km^3 of sediment accumulated on this fan prior to ~ 6.0 ^{14}C ka BP, but subsequent sediment accumulation has been an order of magnitude less (Friele et al., 1999). The floors of major valleys in the Hindukush, Karakoram, and Himalayan mountains are often dominated by huge paraglacial fans, commonly several tens of meters thick (Figure 9), produced by a combination of debris flows and hyperconcentrated flows (Iturrizaga, 2008; Owen, 1989; Owen et al., 1995). Barnard et al. (2006) have demonstrated through the use of surface exposure dating that such fans and associated terraces in the Khumbu Himal are chronologically related to Late Quaternary glacier fluctuations, and proposed that they represent rapid large-scale reworking of glaciogenic sediments during periods of glacier retreat.

Paraglacial valley fills

In glaciated areas, valley-fill deposits often comprise a lower sequence of glaciogenic deposits overlain by an upper sequence of paraglacial deposits. The paraglacial sequence may be exclusively alluvial, or include debris flow, floodplain, alluvial fan, lacustrine, and/or aeolian units in some combination (Owen, 1989; Figures 9 and 10). In the Walensee Valley (Switzerland), for example, the valley fill comprises patchy till overlain in sequence by glacilacustrine sediments, post-glacial lacustrine sediments, and then alluvial gravels. For this site, Müller (1999) calculated average sedimentation rates of 70–100 mm year⁻¹ immediately after deglaciation, reducing to only 3–4 mm year⁻¹ after ~12.3 ¹⁴C ka BP as the surrounding landscape stabilized. Many paraglacial valley fills have been deeply incised by trunk and tributary rivers, reflecting initial aggradation due to abundant sediment supply and then fluvial incision and terrace formation as sediment inputs diminished (Ballantyne, 2002a). Church (2002) has argued that as sediment supply in headward areas of large deglaciated basins is progressively reduced, floodplains in such areas experience net incision, whereas floodplains farther downstream continue to aggrade in response to sediment supply from farther upstream. He concluded that in British Columbia, floodplains up to about 175 km from headwaters are currently

degrading, whereas beyond this distance, aggradation is the norm, though the paraglacial signal in floodplain evolution is now overwhelmed in many catchments by more recent disturbances, particularly the effects of human land use.

Paraglacial Lacustrine Deposits

During deglaciation, proglacial lakes experience a transition from proximal, ice-contact sediment accumulation to ice-distal and then dominantly paraglacial sedimentation. The last is characterized by deltaic progradation (Figure 11) and the accumulation of fine-grained bottom deposits. In mountainous areas, reworking of valley-side glaciogenic sediments by rainstorm-triggered debris-flow events may interrupt the depositional sequence.

Studies of the inland 'fjord lakes' of British Columbia using geophysical profiling indicate that vast quantities of sediment were deposited on lake floors within decades during and immediately after glacier retreat. The largest, Okanagan Lake, is occupied by about 90 km³ of sediment up to 800 m thick. Overlying these deglacial deposits are units up to about 30 m thick, interpreted as representing slower paraglacial sediment influx throughout the Holocene (e.g., Gilbert and Desloges, 1992). A study by Hinderer (2001) of postglacial sediment

accumulation in major valleys and lake basins in the Alps similarly highlights rapid sediment accumulation during and immediately after deglaciation, with a progressive reduction in sediment input during most of the Holocene.

Paraglacial Coasts

Paraglacial coasts are those where remobilization of glaciogenic sediment significantly affects nearshore and offshore sediment budgets. There are two main sediment inputs. First, delivery of reworked glacial sediment by rivers enhances sediment flux in estuarine and fjord-head settings. Second, where glaciogenic sediments crop out at the coast, they are readily eroded by waves and tidal currents, introducing vast quantities of sediment into the nearshore zone. The location and

Figure 11 Paraglacial valley fill and delta progradation, Loch Achtriochan, Glencoe, Scotland.

duration of paraglacial sediment delivery at coasts is determined both by the disposition of glaciogenic deposits relative to the coast and by changes in relative sea level (Forbes and Syvitski, 1994). Where glaciogenic sediments are reworked by coastal erosion, rising sea levels allow wave action to access to new sediment sources; falling sea levels tend to isolate glaciogenic sediment sources from direct wave erosion, but may also result in enhanced sediment input from rivers where lowering base level stimulates river incision into floodplain and valley-fill sediments.

Fjords

In fjords, paraglacial sedimentation commences when retreating ice becomes land-based, and has four main components: (1) delta progradation from the fjord head and lateral tributary valleys, (2) sediment reworking by submarine mass movements and turbidity currents, (3) settling of suspended sediment on the fjord floor, and (4) reworking of glaciogenic sediments around fjord margins (Figure 12). Steep-walled, deep fjords tend to be dominated by (1)–(3); (4) may dominate in shallow fjords such as those of eastern Canada. Rising sea levels may submerge paraglacial deltas but encourage shoreface erosion; falling sea levels trigger erosion of deltas and upvalley outwash deposits, rejuvenating fluvial sediment supply. Glacier retreat from fjords may also result in a drastic fall in base level in tributary valleys, triggering a sequence of rapid landscape responses. Meigs et al. (2006), for example, have described how the recent retreat of the Tyndall Glacier and the opening of Taan Fjord in Alaska resulted in a 400-m drop in base level at the outlets of four tributary valleys, causing rapid fluvial erosion and evacuation of valley-fill sediments, incision of slot gorges in bedrock, and localized

Figure 12 Paraglacial sedimentation in fjords (schematic). The dominant elements are (1) deposition of sand and gravel foresets at the front of a prograding fjord-head delta; (2) slumping of the delta front, generating turbidity currents; (3) settling of suspended particles from a surface sediment plume, and the resultant accumulation of hemipelagic bottom sediments; and (4) reworking of shoreface deposits by wave action. landsliding on valley walls, with associated progradation of fan deltas from tributary outlets. Fjord sedimentation rates generally decline following deglaciation.

Barrier coasts

Paraglacial barrier coasts are those characterized by nearshore sediment accumulations (beaches, baymouth bars, spits, and barrier islands) fed by remobilized glaciogenic sediments. There is a transition from small barriers in rocky inlets where glaciogenic sediment sources are limited to coasts dominated by continuous barrier forms, such as the Beaufort Sea coast of Alaska or the southern Baltic coast. Both progradational and retrogradational barriers occur, depending usually on the balance between sediment supply and sea-level change; under conditions of diminishing sediment supply, barrier retreat, erosion, and destruction occur, and a new barrier system may develop landward of the original (Forbes et al., 1995; Figure 13). Subtypes of paraglacial coasts include those where marine transgression has partly drowned drumlins, which form discrete sources of sediment, and active outwash coasts such as SE Iceland. On barrier coasts where erosion of bouldery till has formed the sediment source, boulder lag deposits have accumulated, forming boulder barricades, pavements, and beaches that armor the shoreface and reduce the sediment supply to barrier structures.

Paraglacial shelf deposits

On many glaciated shelves, the majority of postglacial sedimentation comprises paraglacial deposits overlying distal glacial facies. Paraglacial shelf sediments are characterized by prograding deltaic wedges fronted by mass-flow and hemipelagic deposits. On the Alaskan shelf, for example, paraglacial sediment fines and thins seaward for ~75 km, and has an average thickness of ~55 m.

Wider Implications of Paraglacial Landscape Modification

All glaciated landscapes exhibit evidence of paraglacial modification. In many areas, such modification has been localized, and glacial landforms and sediments are preserved in near-pristine state. Elsewhere, particularly in steeplands, rock-slope adjustment and remobilization of glaciogenic sediment has transformed glacial landscapes. Most postglacial landscape evolution in glaciated environments, whether accomplished by rock-slope failure, landslides, debris flows, rivers, wind action, or coastal erosion, involves glacial conditioning, and hence can be described as paraglacial.

The widespread extent of Holocene paraglacial landscape modification has implications for understanding the long-term evolution of glacial landscapes. Such landscapes are not the result of Quaternary glaciation alone, but of recurrent cycles of alternating glacial and paraglacial erosion and sediment

Figure 14 Model of glacial trough development on bedrock with low rock-mass strength during consecutive glacial and paraglacial phases. The evolving form of the valley is dependent not only on subglacial erosion, but also on paraglacial rock-slope adjustment during nonglacial intervals. Reprinted from Augustinus PC (1995) Glacial valley cross-profile development: The influence of *in situ* rock stress and rock mass strength, with examples from the Southern Alps, New Zealand. *Geomorphology* 14: 87–97. © 1995, with permission from Elsevier.

Figure 15 Rates of glacial sediment transport during glacier expansion. In the initial stages, sediment transport rates are high because of the abundance of readily entrainable sediment in paraglacial stores overridden by the advancing ice. As such sources are progressively exhausted, rates fall to lower levels sustained by subglacial erosion of sound bedrock and sediment delivery to the ice surface. Reprinted from Ballantyne CK (2002) Paraglacial geomorphology. *Quaternary Science Reviews* 21: 1935–2017. © 2002, with permission from Elsevier.

remobilization, transport, and redeposition. In glaciated mountains, paraglacial rock-slope failure, rock-slope deformation, and rockfall alter the form of rockwalls during interglacials; in addition, rock-mass weakening due to paraglacial stress release may determine the foci of glacial erosion during later periods of glacial advance (Augustinus, 1995; Figure 14). Thus, some archetypal forms of glacial erosion such as cirques, arêtes, and glacial troughs may owe their form as much to successive episodes of paraglacial rock-mass adjustment as to glacial quarrying and abrasion. Of more widespread importance is the role played by paraglacial sediment stores during the initial stages of glacier expansion. As such sediment stores provide an abundant source of readily entrainable debris, much of the sediment transported during the initial stages of glacial advance may be of paraglacial origin, rather than eroded from intact bedrock (Ballantyne, 2002a; Ballantyne and Benn, 1994). Where this is the case, the initial stages of glacier expansion are likely to be marked by enhanced rates of glacial sediment transport; when glacial recycling of paraglacial debris is complete, glaciers transport only sediment supplied by ‘normal’ entrainment processes such as subglacial erosion and gravitational debris delivery from valley-side slopes (Figure 15). Just as paraglacial processes are, by definition, glacially conditioned, so some aspects of glacial sediment transport reflect paraglacial conditioning or inheritance.

Talus Slopes

B H Luckman, Western University, London, ON, Canada

© 2013 Elsevier B.V. All rights reserved.

Introduction

Talus slopes are coarse clastic landforms produced by mass wasting processes. They may be broadly defined as distinctive accumulations of loose, coarse, usually angular rock debris at the foot of steep bare rock slopes. The terms talus (North American) and scree (English) are synonymous and refer to both the landform and its constituent material. Alternative terms include debris slopes (Gardner, 1980) and colluvial fans (Blikra and Nemec, 1998). Talus slopes occur in a wide range of environments but most significantly in those where physical weathering processes dominate and gravitational processes deliver freshly weathered products downslope. The production and/or accumulation of debris must be greater than its subsequent weathering or removal and the accumulations must be of sufficient thickness to develop a characteristic morphology independent of the underlying slope. Simple debris veneers only a few particles thick are termed 'debris mantled slopes' (Church et al., 1979). Most studies of talus slopes and talus slope processes have taken place in periglacial or alpine environments. The coarseness of most talus deposits makes them resistant to subsequent erosion: they are often stable, long-lasting elements of the landscape and preserved as relict or inactive forms. Hales and Roering (2005) mapped the distribution of scree slopes in a 80×40 km wide transect across the Southern Alps of New Zealand. They estimate that screes only cover 10% of slopes in the wetter areas west of the divide but may mantle up to 70% of the slopes in the drier eastern part, although only 20–25% are presently active.

Talus slopes vary considerably in morphology, composition, and geomorphic setting. Their basic characteristics depend primarily on the morphology and composition of the flanking cliffs, the geomorphic processes involved in their development, and the topography of the cliff foot zone. Although the dominant process is usually assumed to be rock fall, accumulation of talus material and its subsequent reworking may be the result of many different processes acting singly or in combination. This results in a gradational range of forms with several distinctive end members that nevertheless share many common characteristics.

Rock Fall and Rockfall Talus

Rock fall is the free or bounding fall of rock debris down steep slopes. Rock falls vary in size from individual pebbles to catastrophic failures of several million cubic meters (sturzstrom or rock avalanches). Rubble derived from very large single events is usually unsorted, extends much further from the cliff, and may have distinctive morphological features (e.g., ridges and furrows). Normal talus may subsequently develop below the failure surface, covering the upper parts of the feature. Smaller rock falls ($<10^{-1}$ – 10^2 m³) are the primary process associated

with the formation of talus slopes and may be classified into two types (Rapp, 1960). Massive vertical cliffs are dominated by primary rock falls where detachment is followed by direct transfer to the slope below. Primary rock falls are triggered mainly by pressure release, freeze–thaw activity, or weathering on the cliff face. However, on more complex cliff forms, debris may accumulate on irregularities in the cliff (e.g., benches, gullies) and subsequently be dislodged by other rock falls, snow avalanches, surface water flow, or animals. These secondary rock falls have different magnitude–frequency characteristics than primary rock falls. In an interesting discussion of rockfall provision to talus slopes, Krautblatter and Dikau (2007) identify cliff storage as a significant intermediate step between backwearing (detachment of rock from the host cliff) and rockfall deposition (i.e., delivery to the talus), noting that each may have different triggers.

Rockfall Triggers

The triggering mechanisms for rock falls have been inferred from inventory studies that compare the pattern of rock falls with simultaneous observations of temperature and precipitation. Diurnal and, to a lesser extent, seasonal variations in activity are usually studied by direct inventory or observational methods that record the timing of individual events, often some measure of their magnitude, in combination (where available) with meteorological observations from a proximal site. In some cases, they involve periods of continuous observations (e.g., Gardner, 1969, 1980; Luckman, 1976; Rapp, 1960). More generally, they consist of measurement of the accumulation of debris on marked surfaces over time. These have included boulders, plastic sheets (Krautblatter and Moser, 2009; Luckman, 1978, 1988), wooden traps (Prior et al., 1971), annual snow cover (Matsuoka and Sakai, 1999; Rapp, 1960), or netting (Gray, 1972). Decadal-scale inventory data are usually acquired on the basis of the data collected for other purposes, for example, rock falls onto railways (Lan et al., 2010; Rapp, 1960) or onto roads (Bjerrum and Jorstad, 1968; Luckman, 2008; Pack and Boie, 2002; Weiczorek et al., 1992), or through documentary archives. Such studies can yield rockfall volumes, seasonal, and, sometimes, daily records of activity, and again strongly emphasize the seasonal nature of the processes. Recently, several studies have used dendrochronology to address questions of the frequency and spatial distribution of rock falls from sites in Switzerland and elsewhere (e.g., Moya et al., 2010; Schneuwly and Stoffel, 2008a,b; Stoffel, 2006; Stoffel et al., 2010). These tree-ring studies are usually focused on the runout zones or peripheral areas of talus slopes and use scars and anomalous ring characteristics to identify rockfall events, determine rockfall hazards, or evaluate the efficacy of forests as a protection against rock fall. Examination of the position of damage within the annual ring may allow determination of the seasonality of impacts, although

predictably, the majority of impacts occur within the dormant period of growth (Schneuwly and Stoffel, 2008a,b).

At longer timescales, inventory data have been gathered from accumulated volumes on dated surfaces, for example, by lichenometric studies that date individual boulders (Luckman and Fiske, 1995; McCarroll et al., 1998) or the use of lichens to define a dated surface on which new arrivals can be clearly identified (e.g., André, 1997). These studies may allow determination of rates of rockfall activity on decadal or longer timescales and allow inferences concerning the variation of rockfall rates with changing climates, usually the Little Ice Age (e.g., Luckman and Fiske, 1997; McCarroll et al., 1998) or recent global warming (e.g., Gruber et al., 2004).

These inventory and observational data have led to the almost universal acceptance of frost splitting in bedrock and possibly subsequent ice melt as major trigger mechanisms for primary rock falls. This is based on observations of the diurnal or seasonal distribution of rock falls in the mountain and periglacial environments in which rock falls and talus are most frequently studied. In some cases, degradation (thaw) of mountain permafrost with increasing temperatures has also been identified as a potential rockfall trigger in the alpine zone of mountains (Davies et al., 2001; Gruber et al., 2004). However, detailed observation and modeling of the process is difficult and controversial and has generally been addressed through the context of experimental and theoretical studies on freeze-thaw weathering in periglacial environments. Recent work by Hallet and others (reported extensively by Hales and Roering, 2007, 2009) has suggested that simple volumetric expansion of freezing water within voids or planes of weakness in the rock (the traditional model of freeze-thaw weathering) is not capable of developing the confining pressures necessary to split rocks apart. They suggest that rocks are split by segregated ice growth resulting from migration of water through the rock to the ice lenses at subfreezing temperatures. This process is facilitated by thin interfacial water layers called premelted films and operates at stable temperatures between -3 and -8 °C, well below the fluctuations around 0 °C suggested as significant for conventional freeze-thaw activity. Frequent temperature oscillations across the freezing threshold are therefore unlikely to be a major rockfall trigger under this mechanism. Hales and Roering (2007) present a simple model of the depth and intensity of segregation ice growth in cliffs above screes in New Zealand to show that sites with the predicted maxima in intensity of segregation ice growth correspond with areas exhibiting maximum rockfall erosion rates and scree formation. This process controversy leads directly into the whole literature on the nature and controls of frost or freezing process in periglacial environments which is discussed elsewhere in this volume. Available data on the timing of rock falls usually remain sufficiently imprecise to determine whether falls are associated with the exertion of pressure during freezing (around 0 °C or at lower temperatures of -3 to -8 °C) or related to the release of frost-separated rocks following subsequent melting of the ice. However, the observed spring and fall timing for rockfall events indicates strong temperature dependence of the rockfall-triggering process.

Although less extensively reported, inventory data also indicate that rock falls are often associated with major precipitation events that destabilize loose materials on the slope.

Recently, Krautblatter and Moser (2009) studied accumulation over a 4-year period onto large areas of plastic sheeting (940 m^2) placed on talus slopes in the German Alps. They report that over 90% of the rock falls are associated with heavy precipitation events. However, these are mainly secondary rock falls mobilizing previously weathered materials from the cliff zone. Other studies also note a greater frequency of falls associated with precipitation events (e.g., Luckman, 1976) or relationships with the diurnal temperature regime on the cliff face, particularly periods of solar illumination (Gardner, 1980). These observations may also include records of fairly randomly distributed triggers of secondary falls, including root penetration and wedging, animal or human activity on the cliff, in addition to entrainment of material by downslope movement of rock falls, snow avalanches, or water that dislodges loose surface materials.

In addition to these more-conventionally discussed, climate-related, rockfall triggers, two other major trigger mechanisms are discussed in the literature. Several authors (e.g., Bull and Brandon, 1998; Bull et al., 1994; Guzzetti and Reichenbach, 2010; Mills, 1991) have noted patterns of considerable regional rockfall activity triggered by earthquakes. Additionally, several authors have suggested that unloading or pressure release may be a significant cause of higher rock fall, rock avalanche, or landslide activity. This is particularly cited as an explanation for greater rates of rock fall and talus accumulation inferred to have occurred immediately following deglaciation when the downwasting of ice cover removed lateral support from valley sides previously buttressed by ice, leading to a period of accelerated rates of rock fall or rockslide activity (e.g., Hinchliffe and Ballantyne, 1999; Wieczorek and Jäger, 1996).

Rockfall Movement

When rock falls reach the talus, their subsequent downslope movement may be arrested completely or the rock falls may continue to travel downslope in a series of bouncing trajectories of diminishing length and height, or by rolling or sliding over the surface (see Dorren, 2003; Dorren et al., 2006). These bouncing boulders may produce characteristic 'bump holes' in the surface materials of the slope (Rapp, 1960) and/or considerable damage to vegetation or human infrastructures beyond the talus (see, e.g., Dorren et al., 2006; Schneuwly, 2010).

Movement paths may be very irregular depending on the nature of the impacts and the size and shape of the boulder. Boulders often shatter on their first impact and the independent fragments travel on separate paths. Boulder size and shape are critical. Approximately equidimensional boulders tend to roll or bounce following impact, whereas less compact forms may break up on impact. The downslope movement of disc-shaped boulders can vary considerably. Discoid boulders landing on edge (i.e., with their long-axis vertical) may generate considerable angular momentum, rotating about their center of gravity, and travel 'wheel-like' for long distances downslope. However, should they land on their side (the 'a-b' face) or lose their vertical orientation, they will be quickly arrested or slide only short distances over the surface. Downslope trajectories will also vary with the properties of the surface. For example, where discoid boulders land on snow, the boulders may mire

(landing on edge) or slide depending on their orientation on impact. This erratic behavior is dependent on individual boulder characteristics and the detailed configuration of obstacles in the boulders' path and makes modeling of rockfall paths and runout distances challenging because of the many potentially random elements involved.

Rockfall Hazards

The largest boulders may come to rest some distance below the talus foot, and many talus slopes have a runout zone or a basal fringe of 'out runners' (Blikra and Nemec, 1998). As a result of the obvious hazard associated with rock fall, considerable work has been carried out in modeling rockfall activity. Much of this work is summarized by Dorren (2003), Guzzetti and Reichenbach (2010), and Lan et al. (2010). Dorren (2003) divides these models into empirical, process, and GIS-based models (e.g. Marquinez et al., 2003) and they may further be subdivided into two- or three-dimensional models depending on whether the rock falls are allowed to deviate laterally from a straight downslope path. Many talus slopes have a basal runout fringe of boulders (known as the rockfall shadow zone; Evans and Hungr, 1993) extending beyond the lower limit of the talus. Particular attention has been paid to modeling maximum runout distances in this zone because of the obvious hazard to human structures. Early, two-dimensional, empirical models used Heim's (1932) concept of rockfall fahrböschung (defined as the angle between the top of the slope and the furthest traveled boulder) to define this rockfall hazard zone. Subsequent work from British Columbia by Evans and Hungr (1993) suggests that the outer limit of the shadow zone is best defined by the intersection between the ground surface and a line projected downslope at an angle of 27.5° from the top of the appropriate talus slope.

Three-dimensional modeling of rockfall trajectories has become increasingly prevalent, and numerical, physics-based, models of rockfall trajectories, draped over digital terrain models of potential downslope pathways and supplemented by GIS analyses, have been used to produce sophisticated models of rockfall trajectories (see Guzzetti and Reichenbach, 2010; Guzzetti et al., 2003; Lan et al., 2010 and references therein) that predict or reconstruct rockfall paths and runout distributions. These allow a more accurate prediction of runout distances and may be used to model activity in a variety of settings and at scales ranging from individual sources to regional patterns of activity. For example, Dorren et al. (2006) compare three-dimensional modeling with the results of real-size experiments (boulders ~ 0.95 m diameter) to evaluate the effectiveness of forest cover as protective devices to mitigate rockfall hazards.

Rockfall Talus Morphology

Rockfall talus slopes result from the accumulation of rockfall debris from discrete rockfall events over long periods of time. The plan morphology of talus slopes depends on the form of the cliffs supplying the debris and the morphology of the surface on which the debris accumulates. Relatively simple cliffs, straight in plan view and of uniform or similar geology, tend to produce sheet (straight) rockfall talus slopes lacking

significant lateral variation in their characteristics (Figure 1). However, as the cliffs become dissected, rock falls moving downslope are channeled into gullies or basins, and deposition is focused below couloirs, leading to differential accumulation and the eventual development of talus cones. As well as funneling rock falls, these couloirs channel other gravitational transfer processes down the cliff face (e.g., surface stream flow and snow avalanches) that may result in significant modification of the talus below. Therefore, cones developed below dissected cliffs are rarely simple, single-process (rock fall) forms. The upper slopes of the talus may be gullied or reworked by other processes, resulting in more complex landforms (Figure 2).

Many talus slope profiles are characterized by long straight segments at or about $33\text{--}35^\circ$, often with a strong basal concavity. These slopes have been the focus of considerable field measurement, experimentation, theoretical analyses, and discussion. Initial talus models assumed that these straight slopes were developed by sliding and failure of loose unconsolidated materials (termed dry avalanching or, more recently, grain

Figure 1 A classic straight sheet talus slope developed primarily by rock fall at Small River, British Columbia, Canada. Note the straight slope, slight basal concavity, and 'run out' fringe of boulders beyond the talus foot.

flows) and that the slopes were at the angle of repose of these materials (see Carson, 1977; Statham, 1976). This view was challenged by Statham (1976), who developed a model based on energy expenditure and loss by individual rockfall particles moving over the surface. Extensive reports on measurements of talus slope angles (e.g., Francou and Manté, 1990; Sauchyn, 1986) indicate that measured angles of the straight upper portions of talus slopes are usually between $\sim 32\text{--}37^\circ$ and up to 40° . However, mean talus angles may be as low as $25\text{--}30^\circ$ due to the basal profile concavity. Several authors report differences in mean slope angles as a result of different process combinations (e.g., Church et al., 1979; Sauchyn, 1986). Francou and Manté (1990) propose that talus slopes have a segmented profile: an upper, usually straight slope and a lower section with a basal concavity, separated by a critical angle of $\sim 33\text{--}34^\circ$. They consider that the upper slope is essentially a transport surface, whereas the lower slope characteristics result from both transport and depositional processes. The length and angle of the basal concavity depend on site characteristics, maturity of talus development, and the depositional processes involved.

Direct observation at many sites suggests that dry avalanches (grain flows) on talus slopes tend to be quite small and are confined to relatively small-sized gravel material on the upper slopes (e.g., Van Steijn et al., 2002). Moreover, examination of many talus slopes indicates that the characteristic coarse openwork surface texture is merely a veneer. The openwork surface acts like a sieve: smaller particles or rock chips landing on the slope are trapped or washed into open voids, which become filled with fines and rock chips at depth. Most active rock falls raise dust clouds from the cliffs and talus, and there may also be considerable fine material deposited on the talus from niveo-aeolian processes (Héty and Gray, 2000). Therefore, despite their coarse surface appearance, most talus slopes have considerable quantities of interstitial fine material at depth or exposed on the higher parts of the slope. They are not exclusively formed of the coarse cohesionless material that early models assumed and many subsequent experimental studies simulated.

Surface Processes

Talus creep is the downslope movement of individual particles resting on the talus surface. It results from a combination of many processes, including frost action, running water, rockfall impact, needle ice, animal disturbance, and snow avalanches. This process has frequently been monitored using painted stones or lines on the talus in several long-term studies (e.g., Gardner, 1980; Perez, 1993). Rates of movement on upper talus slopes where fines and smaller clasts are mixed typically average $1\text{--}10\text{ cm year}^{-1}$ (greater where more fines are present), but individual stones may move much greater distances as a result of rock fall or avalanche impacts. The movement of large clasts or those on the lower slopes is much less and generally due to burial or dislodgement by direct impact. Several authors have described a process of dry avalanching of materials or grain flows (van Steijn et al., 2002) – though often seen in modeled talus or in gravel piles, this is usually fairly small-scale on natural talus slopes. On upper talus slopes, frost-susceptible fines at or near the surface favor creep through frost action or,

in some extreme cases, solifluction. Several authors have reported miniature sorted stripes on the upper portion of talus slopes.

Talus Materials

Talus deposits consist of angular, irregular rock fragments with a wide range of sizes. The nature of the debris depends to a large extent on the lithology (or lithologies) exposed in the cliff, as joint and bedding characteristics are primary determinants of the shape and size of talus particles. Most talus slopes show a distinctive increase in particle size of surface materials downslope. This is known as ‘fall sorting’, is often logarithmic in form (e.g., Church et al., 1979; Statham, 1976) and is most marked at the base of the slope. Fall sorting is common on rockfall talus slopes, though not universal, and primarily results from two mechanisms. Larger boulders have greater momentum and therefore tend to travel greater distances downslope. Secondly, the frictional resistance (roughness) of the surface over which the boulder slides, rolls, or bounces is defined by the relationship between the size of the moving boulder and the irregularities of the surface (boulders and voids) over which it is passing. Big boulders are only effectively trapped in large ‘holes’ or when they impact other large boulders or obstacles and lose momentum. Therefore, these boulders come to rest in areas of the talus with boulders (holes) of a similar size. The degree of sorting depends on the slope length, cliff height, and the size and shape of dominant particles. It is best developed on slopes with a wide size range of boulders. Locally random effects or differences in particle shapes may result in the absence of or anomalous patterns of sorting. For example, the frictional properties of snow-covered talus are quite different than snow-free talus: large boulders may be trapped in wet snow or slide over the surface and result in local pockets of coarser materials. Processes other than rock fall may modify these sorting patterns (see ‘Modification of Talus Forms’, below).

Several studies of particle shape indicate a tendency for larger particles on the lower slopes to be more equidimensional (e.g., Perez, 1989). Unless they are small fragments, platy or elongate clasts tend to break up with repeated impacts. Also, ‘blocky’ clasts rolling or bouncing downslope can rotate about any axis with similar efficiency, whereas ‘discs’ or ‘rods’ can lose momentum rapidly if their axis of rotation is changed by impact, for example, from rolling to sliding. Talus fabric is also, to some extent, lithology-dependent. Where clasts are elongate or platy, the fabrics tend to dip downslope and plunge less steeply than the talus slope, giving an upslope imbrication (Perez, 1998). Elongate clasts may show a ‘rolling’ fabric (long axis across slope) or a sliding fabric (long axis downslope; Blikra and Nemec, 1998). However, given greater equidimensionality of debris on many lower slopes, fabrics are often, as might be expected, fairly random, unless the talus material is predisposed to an elongated shape by the lithologic characteristics of the material or emplaced by a process favoring sliding; for example, Perez (1989) describes a strong downslope orientation for blocks at Lassen Peak where emplacement is dominated by sliding over a seasonal snow cover.

In recent years, there have been detailed studies of the sedimentology of talus and related deposits (Bertran et al.,

1997; Blikra and Nemec, 1998; van Steijn et al., 1995, 2002) that have developed criteria to differentiate between talus, snow avalanche, debris flow, and other mass-wasting deposits found within talus-like formations. Blikra and Nemec characterize talus as a colluvial deposit consisting of “tongue shaped beds with marked upslope fining, normal grading and mainly openwork texture” that may show a ‘rolling,’ downslope or random fabric depending on the dominant process and the lithologically determined shape of clasts. The deposits of most other processes that influence talus slope development contain a matrix of fines. However, the differences in sedimentological characteristics in these sediments are subtle and difficult to categorize precisely in the absence of surface morphological evidence.

Bedded or ‘stratified screes’ (grèzes litées) were first described from periglacial deposits in Northern France (see van Steijn et al., 1995). They are composed of platy or friable calcareous rocks that show dipping beds of coarser openwork gravels alternating with matrix-filled gravels. Studies of these deposits suggest that the openwork beds result from dry grain flows, whereas the matrix-supported deposits are associated with debris flows, sheet flow, or quasialluvial processes. Recently, Hétu and others (Hétu and Gray, 2000; van Steijn et al., 2002) have described contemporary analogs for these deposits from talus slopes developed from friable, shaley materials in Gaspésie, Québec. Hétu has also described small ‘frost coated clastic flows’ (FCCFs) that are similar to grain flows, but the clasts are ice-coated and move downslope as small 0.5–1.5 m wide flows at $2\text{--}6\text{ m s}^{-1}$ on slopes between $\sim 36\text{--}24^\circ$. The alternation of matrix-rich beds with finer clasts with these coarser openwork deposits can lead to the development of stratified screes. This may be a realistic analog for periglacial conditions in Northern France during the last glaciation. Van Steijn et al. (2002) indicate that dry flows are seen in all climates and are not necessarily periglacial phenomena. FCCF are, however, formed in periglacial environments, with suitably friable lithologies, a high frequency of freeze-thaw cycles and a limited snow cover. They suggest that dry avalanche deposits and FCCFs may be differentiated based on the angle of slope: dry flows cease at angles below $\sim 34^\circ$, whereas FCCFs may flow on slopes as low as 24° (Van Steijn et al., 2002).

Modification of Talus Forms

As talus deposits accumulate, geomorphic processes other than rock fall may rework loose surface materials, modifying talus morphology and surface characteristics. These changes are most frequently seen in periglacial or alpine environments where long-continued modification of talus can lead to the development of distinctive landforms associated with snow avalanches, debris flows, and permafrost creep.

Snow Avalanches

In arctic or alpine areas, snow avalanches running down the cliff face may entrain material and deposit it on the talus below (Rapp, 1960). However, as these snow avalanches move over the talus, they may also erode or incorporate loose surface

Figure 3 Talus slopes modified by extensive snow avalanche activity resulting in avalanche boulder tongues, Pallenvagge, Abisko Mountains, Sweden. The darker talus is more stable and heavily lichen-covered, and the lighter areas show surface reworking by snow avalanches. The basal profiles of the well-developed avalanche tongues (center and left) have strong basal concavities.

material, frequently exposing fines at the surface. This material is transported downslope, where it is deposited on coarser material as a scattered cover of precariously positioned smaller boulders or rock fragments, let down from an ablating snow cover. These phenomena are known as avalanche or perched boulders (Jomelli, 1999; Luckman, 1988; Rapp, 1960). The upper, eroded slopes show little size sorting and may be stripped of loose materials, but there is a rapid increase in mean grain size toward the base, where avalanched material is mixed with coarse blocky rockfall debris. Long-continued or intense avalanche activity may carry debris well beyond the limits of the talus, resulting in a loose scatter of coarse debris or the development of an avalanche boulder tongue (Jomelli and Francou, 2000; Luckman, 1978; Rapp, 1959). These ‘roadbank tongues’ can be recognized by a raised tongue of debris extending beyond the original talus, often with an asymmetric cross-section and a smoothed beveled top, flanked by steep side slopes and a lobate front. Talus slopes modified by avalanches exhibit a pronounced basal concavity, a strong size sorting of surface debris at their lower end and often extend a considerable distance beyond the toe of adjacent, normal rockfall talus across slopes of as little as $8\text{--}10^\circ$ (Figure 3).

Debris Flows

The upper portion of talus slopes contains considerable fines mixed with small rock clasts. Many talus cones are dissected by small gullies that head at the base of the cliff and decrease in size downslope. During heavy, intense rainstorms, water is channeled down the couloirs onto the talus below, mobilizing debris within the gullies on both rock wall and talus, saturating the apex area and generating small hillside debris flows. Single or multiple examples of these features with their characteristic channels, levee margins, and terminal lobes may be generated on the talus, partially covering earlier rockfall-deposited material (Figure 4). Once initiated, these headward gullies will continue to function as pathways for subsequent events, ultimately producing an irregular, often somewhat radial, pattern

Figure 4 Talus cones, extensively modified by debris-flow activity, Tanquary Fjord, Ellesmere Island, Canada. Note the characteristic levees and terminal lobes of the debris flows and the lower mean slopes of the heavily modified 'alluvial' talus.

Figure 6 Talus cones showing modification into a variety of rock-glacier forms by permafrost creep, Tanquary Fjord, Ellesmere Island, Canada.

of debris-flow sediments extending downslope across the lower slopes of the talus. Subsequent erosion or dispersal of these materials takes place by later debris-flow events or snow-avalanche activities ([Figure 5](#); [Luckman, 1992](#)). These forms have been christened 'alluvial talus' and over long periods of time, they may develop into high-angle debris-flow or alluvial cones.

Protalus and Rock Glaciers

Talus slopes are most frequently studied in periglacial environments. At some talus sites, a perennial firn (snow) patch may develop at the base of the slope. Rockfall or avalanche debris landing on this icy surface slides to the base, accumulating as a ridge which has been termed a protalus rampart or nivation ridge.

In many relatively dry, cold alpine areas, thick talus accumulations contain permafrost. The continued buildup of talus and ice in the basal talus may lead to the development of a convex bulge (protalus bulge) in the lower talus. Subsequent

deformation and creep of this rock-ice mixture leads to rock-glacier development that transports the coarse talus material away from the base of the slope ([Figure 6](#)). Rates of movement are rarely more than a centimeter per year (see [Rock Glaciers and Protalus Forms](#)).

Rates of Development

Talus slopes below rock cliffs are a measure of the accumulated removal of debris from these cliffs and therefore have been the focus of many attempts to determine rates of rockwall recession and landscape change in a variety of environments. Attempts at measurement have been carried out using a number of techniques at different timescales. Short-term measurements involve determination of the accumulation on marked surfaces for periods of up to 10–15 years (e.g., [Luckman, 1988](#); [Rapp, 1960](#); [Sass and Wollny, 2001](#)). Such estimates are hampered by spatial (the relatively small proportion of the talus sampled) and temporal (only a few years) sampling problems. An extension of these studies has used lichenometry to estimate accumulation rates over longer periods of time (>1–300 years; [André, 1997](#); [Luckman and Fiske, 1995](#); [McCarroll et al., 1998](#)). Finally, there have been several attempts to calculate volumes based on well-defined cones, by interpolating the sub-talus bedrock profile from adjacent slopes ([André, 1997](#); [Hales and Roering, 2007](#); [Rapp, 1958](#)). In recent years, the potential for error has been reduced by using ground-penetrating radar to estimate the sub-talus surfaces ([Sass and Wollny, 2001](#)). The rates determined by all of these measures are invariably fairly low, often <1 cm per millennium but exceptionally up to 1 m. They vary with environment, techniques used, and cliff geology, with little systematic pattern (see summaries in [André, 1997](#); [Krautblatter and Dikau, 2007](#); [Sass and Wollny, 2001](#)). In an attempt to examine these controls, André's studies in Spitzbergen indicate that rates of rockwall recession rarely exceed 1–2 m during the Holocene, except for sites with glacier-related stress relaxation on rock walls, highly frost-susceptible bedrock, or

exceptionally high cliffs. Krautblatter and Dikau (2007) present an extensive discussion of these estimates and discuss a series of theoretical models of the relationships between rock-wall recession (backwearing), intermediate storage on the cliff, and rockfall supply to the talus below.

The low contemporary estimates of debris production and the presence of many inactive talus slopes in formerly glaciated areas have led to the suggestion that much of the talus accumulation in these areas is paraglacial in origin; that is, these features accumulate rapidly during a period of accelerated mass-wasting activity immediately following deglaciation due to the release of confining pressure in the rock walls and exposure to atmospheric conditions (André, 1997; Ballantyne, 2002; Luckman and Fiske, 1995). Mills (1992) has documented talus slopes, 80–100 m thick with well-developed morphology and fall sorting that have formed over an 8-year period in the crater of Mt St. Helens. This indicates that classical talus forms can develop quite rapidly, although in this case, the process is considerably accelerated by abundant freshly shattered bedrock and continued earthquake activity. Nevertheless, the presence of relict or vegetated talus in many areas and relatively low rates of accumulation in some contemporary studies have led to an interesting discussion as to whether the high rates of accumulation reflect a paraglacial (induced by accelerated rockwall failures following glacier recession) or periglacial (severe freeze-thaw activity in a colder postglacial climate) origin (see Ballantyne, 2002).

Paleoenvironmental Significance

In recent years, some attention has been directed to the paleoenvironmental significance of talus slopes and deposits. Many of these studies involve the examination of gully sections or trenches cut in the upper parts of talus that are presently inactive (Curry and Black, 2003; Hinchliffe, 1999). Alternating layers of openwork clasts interbedded with finer grade deposits, peats, or paleosols are interpreted as intervals of renewed rockfall activity and stability, respectively, related to cooler and/or wetter climate intervals that can be dated by ^{14}C . Hétu and Gray (2000) describe colluvial sequences interbedded with paleosols that reflect alternating process regimes during the Little Ice Age and are, in part, conditioned by the changes in the forest cover. Similarly, explanations for grèzes litées deposits invoke alternating periods of gravitational (dry avalanching or FCCF deposits) and debris-flow/slopewash deposits attributed to periods of wetter and/or colder intervals. However, although these sediments reflect different processes, deposition on talus slopes is discontinuous and episodic, and individual stratigraphic units may be quite thin. The dating control is often limited and the deposits may only represent a single, almost instantaneous event, for example, a debris flow or single depositional event (see Krautblatter and Moser, 2009), rather than decade-century intervals with a different climatic regime. Contemporary studies of rainfall-triggered debris-flow activity indicate that relatively low-frequency storms may trigger synchronous events over areas of $>10\text{ km}^2$ (Luckman, 1992; Rapp, 1960), producing similar stratigraphic evidence on different talus slopes. Similarly, although heavily lichen-covered rock fall or avalanche debris that occurs beyond

the limits of contemporary activity indicates that there have been larger events in the past, it does not necessarily indicate that there have been changes in the rate or intensity of activity. It may simply indicate that these larger scale events have recurrence intervals that are greater than the effective range of the dating technique used.

Therefore, given that the magnitude-frequency spectrum of processes that contribute debris to talus slopes is poorly defined and it is difficult to determine whether individual deposits represent a single event or multiple events, paleoclimate inferences from these deposits should be made with caution. In many cases, the deposits may represent individual high-magnitude, infrequent events that have little or no relationship to 'average climate' conditions.

Thermokarst Topography

C R Burn, Carleton University, Ottawa, ON, Canada

© 2013 Elsevier B.V. All rights reserved.

Introduction

Thermokarst terrain exhibits a pitted relief formed from the melting of ground ice. 'Thermokarst' is used widely to describe all processes and landforms that are associated with melting ground ice, but thermokarst, or thaw, lakes are probably the most well-known features (Figure 1; French, 2007). Thermokarst processes are generally only considered with respect to permafrost terrain, and soil displacement due to melting of seasonal frost is not included. Thermokarst topography and landforms are found throughout the permafrost regions, wherever ground ice is exposed or melted. Thermokarst features are uncommon in bedrock areas, but may occur locally in depressions where a sedimentary cover, including ground ice, has accumulated.

The geotechnical significance of permafrost derives from the presence of ice in the ground, and the terrain instability that follows thawing of ice-rich permafrost. The volume of water released as ice melts is commonly higher than the saturation water content of the soil, and so pore-water pressures rise. In flat terrain, consolidation of thawed soil leads to subsidence of the ground and an undulating topography, because the rate and extent of thawing is spatially variable. This variability stems primarily from the heterogeneous distribution of ground ice. In sloping terrain, high pore-water pressures lead to a reduction in effective stress and loss of soil strength so that slopes may fail. Landslides are common in permafrost terrain that has been burned by forest fire, because the resulting change in surface characteristics, not the heat of the fire, raises ground temperatures and leads to permafrost degradation (Burn, 1998). Thermokarst processes may be problematic for infrastructure and design of construction projects, which modify surface conditions and warm the ground. There are numerous examples of structures that have become unserviceable due to melting of ground ice beneath them (Figure 2; Crawford and Johnston, 1971; French, 1975). While the thermal effects of artificial surfaces can be modeled reliably (Andersland and Ladanyi, 1994), the ground-ice distribution at a site is commonly less well known and the source of most unforeseen incidents.

Permafrost and the Active Layer

Permafrost is the ground that remains at or below 0 °C for 2 or more years. Permafrost terrain consists of a seasonally thawed active layer underlain by perennially frozen ground. The base of the active layer is at the top of permafrost. Continental permafrost is found where the climate sustains frozen ground, with vast extents in northern regions of Canada, Alaska, and Siberia. Alpine or plateau permafrost occurs at high elevation, in areas where continental permafrost is not found. There are areas of permafrost in the major mountains of the world, and an extensive distribution in the Tibetan Plateau. In total, about

15% of the land surface of the Northern Hemisphere is underlain by permafrost (Zhang et al., 2000).

Permafrost is classified by the proportion of the exposed land area of a region that contains perennially frozen ground. By definition, permafrost is considered continuous where it underlies more than 90% of the terrain. In these areas, the spatial mean ground temperature is well below 0 °C, commonly <−5 °C, and only a few locations have a microclimate that does not support permafrost. The amount of unfrozen ground increases in the discontinuous permafrost zones, so that the proportions of perennially frozen ground in the extensive and sporadic discontinuous permafrost zones are 90–50% and 50–10%, respectively (Zhang et al., 2000). Isolated patches of permafrost occur where less than 10% of the ground supports permafrost. The spatial mean ground temperature increases with the proportion of unfrozen ground. Thermokarst features occur in all permafrost regions because the critical requirement is ground ice, while surface disturbances may raise ground temperatures above 0 °C at any location if either permafrost is exposed to the atmosphere, or water accumulates to depths exceeding the winter-ice thickness.

The thickness of the active layer depends on a variety of factors, principally the temperature and duration of the summer, thermal properties of near-surface materials, ice content of the soil, and the nature of heat transfer in the near surface (Williams and Smith, 1989). However, conditions during the preceding freezing season are also significant, particularly the average winter temperature and snow depth, which control the temperature of the active layer before thawing begins. The deepest active layers are found in coastal beaches and lake shores, where convection enhances the transfer of heat to the thawing front, and in bedrock where there is relatively little ice to melt each summer. Deep active layers are also common in well-drained dry ground, such as gravel. Relatively shallow active layers are found in peatlands, where evaporation within damp moss maintains cool ground temperatures and preserves permafrost. In the Northern Hemisphere, the southern limits of continental permafrost are found in peatlands.

Near-Surface Ground Ice

Characteristically, there is an ice-rich zone at the top of permafrost, just below the active layer. This layer may have particularly high ice contents in fine-grained sediments in moist environments (Figure 3), but it has also been observed in bedrock. If the active layer deepens and permafrost thaws, then the near-surface ground ice will melt. The presence of this ice-rich horizon is the basis for thermokarst development, and the reason that permafrost terrain is considered sensitive to disturbance. Commonly, the ice occurs in subhorizontal lenses of centimeter thickness, segregating similarly sized beds of sediment (segregated ice lenses), or as bodies of almost pure 'massive' ice.

Figure 1 Thermokarst lakes near Mayo, Yukon Territory, Canada (see [Burn and Smith, 1990](#)). (a) In July 1988; (b) in July 1998, showing expansion that led to the merging of two lakes. Photographs by C.R. Burn.

Figure 2 Two buildings in Dawson City, Yukon Territory, that are no longer in use because of thaw settlement beneath them. Photograph taken in July 1994 by C.R. Burn.

Figure 3 Ice-rich near-surface permafrost exposed in a slumped block at Pelly Island, western Arctic coast, Canada. The block is an ice-wedge polygon that was undercut by shoreline erosion, and split along the ice wedges. There is a black organic horizon at the top of permafrost, an ice vein has been truncated by the early Holocene thaw unconformity, and an ice wedge is exposed on the left side of the block. Determinations of the near-surface volumetric ice content of permafrost on the island ranged up to 58% ([Burn, 1997](#)). Photograph taken in August 1993 by C.R. Burn.

The most common forms of massive ice are ice wedges that form from repeated infilling of thermal contraction cracks by snow melt. These linear bodies are V-shaped in cross section, are commonly capped by the active layer, and extend downward for about 5 m ([Figure 3](#)). They form outline networks of tundra polygons, which are easily seen in lowlands, but are obscured on hill slopes by soil movement. Other massive icy bodies may be formed near the base of the active layer by injection of water during the autumn freezeback, due to pressures generated during freezing of coarse-grained sediments. In some locations, bodies of massive ice several meters thick may be buried glacier ice, remnant from the last glaciation, or masses formed during regional aggradation of permafrost.

Where the ice is distributed within the mineral soil, the ground is particularly ice rich in the upper 2 or 3 m of permafrost ([Figure 3](#)). The ice-rich zone has been called the ‘intermediate layer’ of permafrost, because it may thaw episodically due to climate variation ([Shur et al., 2005](#)). However, in some locations, these sediments were formerly within the active layer only during the Holocene climatic optimum, and have accumulated ice during the subsequent cooling and thinning of the active layer ([Burn, 1997](#)). Similarly ice-rich horizons are found just below the active layer in depositional environments, where the top of permafrost has aggraded with sedimentation or peat growth. The ice enrichment occurs due to water being drawn along the ground-temperature profile into freezing soil and permafrost at the end of summer and during freeze back of the active layer ([Mackay, 1983](#)).

Massive ice and individual ice lenses may be nearly 100% ice, although air bubbles are commonly distributed through the ice body. The ice-rich zone of segregated ice lenses is generally also of high ice content. In sandy materials, the volume of ice may be 30% greater than the saturated volume of thawed soil, but in fine-grained sediments, the super saturation may be greater ([Burn, 1997](#)).

Disturbances to Permafrost

The ground surface temperature, T_s , and thermal properties of ground materials control the heat flux through the active layer

into permafrost. T_s is controlled by the surface energy balance, providing a solution for

$$Q^* = Q_H + Q_E + Q_G \quad [1]$$

where Q^* is the net radiation at a site, Q_H is the flux of sensible heat between the surface and the atmosphere, Q_E is the latent heat flux (evaporation or condensation) between the surface and the atmosphere, and Q_G is the ground heat flux between the surface and underlying soil. Changes to surface characteristics alter these fluxes. For instance, drying of the surface reduces Q_E , and a higher T_s is then required to increase Q_H and Q_G to maintain their equivalence with Q^* . In permafrost regions, changes in surface conditions characteristically lead to either deepening of the active layer, long-term degradation of permafrost, or both (Mackay, 1970). Deepening of the active layer is a result of surface warming in summer, but increases in snowfall or winter temperatures may also lead to an increase in thaw depth.

In addition to T_s , the thermal properties of surface materials are critical to the stability of permafrost, because they control the heat flux through the active layer. In a substantial portion of the permafrost region, especially in the discontinuous zones, perennially frozen ground is covered by a blanket of peat and mosses. This low-density organic layer has a low thermal conductivity and is commonly moist. As a result of its damp state, heat supplied from the surface is used in evaporation rather than warming the ground, thus maintaining cool conditions at depth. The organic layer is critical to the stability of the active layer, and disturbance of the surficial organic cover leads to thawing of near-surface permafrost (Mackay, 1970; Zoltai, 1993).

Forest fires create the most widespread surface disturbances in permafrost regions. Fires change several surface characteristics to influence the surface energy balance (Figure 4).

First, Q^* increases at the ground surface following a reduction in shade and a decrease in surface albedo from charred debris. Second, the organic horizon may be incinerated, removing its effective insulation, and drying the surface. Third, the reduction in canopy cover and accumulation of deadfalls increases snow depth, reducing heat loss from the ground in winter. Burn (1998) measured an increase in mean annual soil temperature, at 20-cm depth, of 1.25 °C between proximal

burned and unburned sites in southern Yukon Territory, where an intense fire in 1958 had incinerated the surface organic horizon. The increase in ground temperature prompted long-term permafrost degradation at the burned site. A 25-year record of active-layer development following fire at Inuvik, Northwest Territories, detected initial deepening of the active layer, but aggradation of permafrost as vegetation recovered (Mackay, 1995).

Deepening of the active layer leads to subsidence of the ground where near-surface permafrost is ice rich (Mackay, 1970). Figure 5 shows that active-layer deepening leads to lowering of the surface of permafrost by the sum of the increase in active-layer thickness and ground subsidence. As the ice content of permafrost increases, for a given increase in active-layer depth, the surface subsidence increases. Where the degree of surface disturbance or near-surface ice content is spatially variable, subsidence will vary and thermokarst topography will develop. Mackay (1970) and French (1975) provide several examples of surface disturbances that led to ground subsidence.

Permafrost Degradation

Long-term degradation of permafrost will occur if the mean annual ground temperature rises above 0 °C. Such long-term thaw is a function of the mean surface temperature, T , the volumetric latent heat in permafrost, L , and the thermal conductivity of thawed materials, λ . The Stefan solution has been successfully used under field conditions to approximate the relation between the depth of thaw, z , and the time, t , since thawing began (Burn, 1998, 2000; Burn and Smith, 1990):

$$z = \sqrt{(2\lambda Tt/L)} \quad [2]$$

or,

$$z = b\sqrt{t} \quad [3]$$

$$b = \sqrt{(2\lambda T/L)} \quad [4]$$

This model assumes that all heat entering the ground is used to thaw permafrost, rather than warm thawed soil above

Figure 4 Change in surface conditions wrought by a forest fire in the boreal forest of central Yukon Territory, Canada, during July 1995. The Klondike Highway was used to control the fire. (a) East of the highway where the forest was burned; (b) to west of the highway, with undisturbed forest. Photographs by C.R. Burn.

Figure 5 Thaw consolidation of permafrost terrain due to deepening of the active layer. The presence of excess ice in near-surface permafrost leads to lowering of the ground surface as the active layer deepens, and an absolute lowering of the permafrost table greater than the increase in active-layer depth. Diagram by S. Smith, Geological Survey of Canada. Reproduced from Mackay JR (1970) Disturbances to the tundra and forest tundra environment of the western Arctic. *Canadian Geotechnical Journal* 7: 420–432.

the permafrost or the permafrost itself, and that the surface temperature history involves a step change to the value that generates thawing. The assumptions are reasonable, because the latent heat of fusion is one to two orders of magnitude greater than the heat required to raise the same volume of soil materials by 1 °C, and because natural changes in surface conditions require decades for recovery of vegetation to former conditions. The rate of permafrost degradation may be obtained by differentiating eqn [3] with respect to time:

$$\frac{dz}{dt} = \left(\frac{b}{2\sqrt{t}} \right) \quad [5]$$

Therefore, the rate of permafrost degradation declines with time since disturbance.

The Stefan solution is a one-dimensional analysis of permafrost degradation, and may be applied to the rate of thaw beneath a disturbance. However, at the edge of disturbances heat flow is both vertical and horizontal, in response to the temperature gradients across the boundary of the disturbance. In this case, the rate of horizontal expansion of the disturbance may be obtained from eqn [5], with $t=1$ (Burn and Smith, 1990). The relation may be applied when ground-ice conditions are spatially continuous. Commonly thermokarst disturbances are halted as local ground ice is exhausted.

Thermokarst Lakes

Ponding of water in depressions formed by melting of near-surface ground ice commonly leads to deepening of the active layer and degradation of permafrost. While the depth of a lake is less than one-half to two-thirds of the maximum winter-ice thickness, permafrost may be maintained beneath the lake, but once the pool exceeds this amount, the mean annual water-bottom temperature rises above 0 °C, and permafrost is unsustainable beneath the pond (Figure 1). As a result, the pond deepens and expands. The rate of expansion depends on the ground-ice content of near-surface permafrost. Figure 1 shows actively expanding thermokarst lakes in central Yukon Territory, growing in ice-rich glaciolacustrine sediments (Burn and Smith, 1990). These lakes are enlarging at their shores at a rate of about 0.5 m year⁻¹.

Figure 6 Tundra lake on Richards Island, western Arctic coast, Canada, showing the dark water of the deep central pool, and scars of retrogressive thaw slumps around the lake. Photograph taken in August 1991 by C.R. Burn.

There are numerous thaw lakes in permafrost regions because the frozen ground inhibits drainage. The Arctic coastal plains of northern Alaska, Siberia, and Canada's western Arctic contain thousands of lakes (Figure 6), but most of these are thousands of years old (Hinkel et al., 2003; Rampton, 1988). In many cases, the lakes have reached a steady state with the surrounding permafrost, so that the taliks of unfrozen ground beneath the lakes are of constant size (Burn, 2002). The taliks may be perched above permafrost for small lakes, but for large lakes, the talik may penetrate permafrost. The width of lakes where the taliks penetrate permafrost depends on the temperatures at the lake bottom and in the surrounding permafrost, and the geothermal gradient (Mackay, 1963). Many tundra lakes have shallow littoral terraces containing permafrost (Figure 6), which may extend for over 100 m from the shore. The terraces shield permafrost around the lake from thaw, so these lakes are quasistable. Degradation of permafrost around these lakes may be initiated by terrestrial processes such as mass movements, rather than lacustrine effects.

The expansion of thermokarst lakes follows eqn [2] (Burn and Smith, 1990). The rate of deepening depends on the ground-ice content, thermal conductivity of thawed lake-bottom sediments, and on the lake-bottom temperature.

Figure 7 Daily mean lake-bottom temperatures recorded in 2001 at 10-m depth in the central pool of Todd Lake, a tundra lake near the western Arctic coast of Canada (Burn, 2002), and at 5-m depth in Lake 2 at Mayo (Burn and Smith, 1990). Todd Lake is well mixed by forced convection in summer, but Lake 2 is shielded from the wind and is poorly mixed. The series are plotted from daily data, but the symbols are plotted only every 5 days for clarity. The annual mean temperature at both of these depths is 3.5 °C.

Lake-bottom temperature is sensitive to the extent of mixing in the water column. Figure 7 indicates the annual temperature cycle in a small thermokarst lake in the boreal forest near Mayo, Yukon Territory, and a tundra lake near Canada's western Arctic coast. The tundra lake is well mixed in summer, so that warming of the lake bottom occurs rapidly. The forest surrounding the other lake acts as a wind break, and the lake is not mechanically mixed. Hence, warming at the lake bottom occurs by conduction, although cooling in fall is by density-induced free convection. A result is that the mean annual lake-bottom temperatures are similar at the sites. These data illustrate the independence of lake-bottom temperatures from climate, for the mean annual air temperature at Mayo is about -3°C , while at the coast it is about -10°C .

Thermokarst lakes may cease growing if the surrounding ground ice is exhausted, the basin becomes infilled by sedimentation or plant growth, or the lake drains. Drainage, or partial drainage, of thaw lakes is well documented, and commonly occurs if the active layer surrounding a lake deepens to below water level, so that once flow begins, it accelerates from a trickle to a torrent (Mackay, 1997). Drainage is rarely complete, and residual ponds are common in drained basins. Extensive depressions may be exposed by drainage of large lakes. These are best-known from Siberia, where they are called 'alasses.'

Retrogressive Thaw Slumps

Thaw slumps are the most active geomorphological features of permafrost terrain. Erosion of river banks, along the shores of lakes, or at the coast, may expose permafrost and initiate ablation of ice-rich ground. In river banks, high water during the spring flood may remove covering sediments and overhanging mats of peat, or undercut banks that subsequently collapse to reveal ice-rich ground. Along lake shores and at the coast, erosion during storms may similarly undercut ice-rich ground which is subsequently exposed (Figure 3). Once exposed to air temperatures above 0°C , or to direct insolation, the ice-rich ground may thaw and turn to a mud slurry due to the high water content. This mud falls to the base of the

exposure and flows down to the water body. The exposed permafrost commonly forms a steep headwall ranging from 20° to 90° (Figure 8(a)), while the thawed materials accumulate in a more gentle foot slope of inclination between 3° and 15° , stretching from the foot of the headwall to the water body (Figures 8 and 9). Headwall ablation rates of up to 16 m year^{-1} have been measured, but more commonly the headwall retreat is about 10 m year^{-1} in a range of environments (Burn and Lewkowicz, 1990). Thaw slumps continue to develop until the headwall enters sediments of low ice content, as with the slump on Figure 1; the headwall is covered by an insulating layer of thawed debris, commonly an overhanging peat mat, or the terrain geometry allows the foot slope to rise and cover the permafrost. The longevity of thaw slumps therefore depends on ground-ice distribution and local topography. Many thaw slumps near the coast are rejuvenated by continuing coastal erosion, for instance, the slumps in Figure 9 are within a larger stabilized area.

Direct thawing of permafrost occurs in the ablating headwall, where the gradient is too steep to retain thawed material on the surface. In contrast, on the foot slope, thawed material accumulates to shield the underlying permafrost. The disturbance of surface conditions from the previously undisturbed vegetation cover may be sufficient to cause long-term thawing of the permafrost beneath the foot slope. The foot slope commonly develops a deeper snow cover than the surrounding undisturbed ground because the rough accumulation of surface debris prevents drifting. In the boreal forest, trees are toppled by the thaw slump, so shading of the surface is less on the foot slope than in undisturbed ground. In the boreal forest, such disturbance raises the mean ground temperature above 0°C , and permafrost is only reestablished after vegetation succession restores the original forest. An increase in mean annual ground temperature of about 4°C over undisturbed conditions has been measured at the thaw slump illustrated in Figure 8 (Burn, 2000).

Kokelj et al. (2009) pointed out that at many tundra lakes in western Arctic Canada retrogressive thaw slumps reinitiate after stabilization, and that there may be a depression in the lake bottom close to the lake shore adjacent to thaw slumps.

Figure 8 A retrogressive thaw slump near Mayo, central Yukon Territory, Canada. (a) Ice-rich glaciolacustrine sediments exposed in the 10-m-high headwall (June 1984); (b) overview of the slump showing the headwall and footslope of about 350 m between the headwall and Stewart River (August 1984). River erosion of ice-rich permafrost initiated the slump in 1949, and the headwall retreated from the river at up to 16 m year^{-1} . Photographs by C.R. Burn.

Figure 9 Retrogressive thaw slumps initiated by coastal erosion of Pelly Island, western Arctic Canada. Photograph taken in August 1993 by C.R. Burn.

They demonstrated that the annual mean ground temperature beneath the footslope may be higher than in the adjacent tundra due to snow accumulation on the rough footslope in winter. As a result, lake talik configuration adjacent to the slump deepens locally. The deepening increases thawing of permafrost at the foot of the slump and leads to reinitiation of the slump in the foot print of the original feature.

Active-Layer Detachments

In permafrost regions, failures commonly occur on low-angled slopes (McRoberts and Morgenstern, 1974). Characteristically, the failures occur during relatively warm summers or after forest fires (Harris and Lewkowicz, 2000). The failure involves detachment of the active layer from the underlying permafrost so that it may slide downslope (Figure 10).

Such active-layer detachments have also been called 'skin flows' (McRoberts and Morgenstern, 1974) and 'active-layer glides' (Mackay and Mathews, 1973). The detachment accumulates at the base of the slope as an involuted sheet, and may override and fan out there.

The development of active-layer detachments follows thawing of ice-rich ground at the bottom of, and below, the active layer. Water released by thawing excess ice is, by definition, of greater volume than the pore space in mineral soil, so the pore-water pressure increases. This reduces the effective stress at the thaw front, and may lead to failure on even gentle slopes (Harris and Lewkowicz, 2000). Slope stability may be maintained if the excess pore water drains as the thawed soil consolidates, reducing the pore pressure. The critical soil parameter is the thaw consolidation ratio, R (McRoberts and Morgenstern, 1974):

$$R = b/(2\sqrt{c_v}) \quad [6]$$

where c_v is the coefficient of consolidation. The shear strength of the soil may decline over time due to slow deformation at the base of the active layer toward the end of summer, and reduce the excess pore pressures required for detachment (Harris and Lewkowicz, 2000). Active-layer detachments are common in fine-grained soil and diamicton, where the hydraulic conductivity is low and consolidation is slow, but they may occur in other materials if the rate of thaw is sufficiently high. They occur in clusters, both in space and time, due to their association with particular events and sedimentary materials.

Sedimentary Record

The sedimentary sequences in thermokarst basins contain primary deposits laid down during initial subsidence and secondary deposits transported into the basin. The primary deposits may contain disorganized remnant vegetation, particularly wood pieces, that grew before thermokarst initiation, and shells from pond fauna (Burn and Smith, 1990). In the boreal forest, trees either topple into thermokarst lakes or are gradually submerged (Burn and Smith, 1990), and such organic matter is well preserved in the anaerobic lake bottom. Primary deposits of thaw slumps are massive clastic sediments, due to thawing and consolidation of soil in the foot slope, containing dispersed organic accumulations of peat or

Figure 10 Active-layer detachment failure on Pelly Island, western Arctic coast, Canada, August 1993. (a) Aerial view of failure; (b) failure surface showing slickensides. The slickensided surface of exposed ground indicates that the active layer has moved intact over permafrost. Photographs by C.R. Burn.

woody material, representing debris that fell into the slump. The sedimentary structure left by active-layer detachment is convoluted, as a result of deformation of the active layer at the base of the slope.

Secondary deposits accumulate in thermokarst basins from mass wasting of the surrounding slopes (Murton, 1996). These follow a three-part sequence governed by the evolution of the basin. First, clastic sediments accumulate in the basin from thaw slumping or detachment around the edges of the basin or lake. Second, as ground ice around the basin is exhausted and as slope gradients decline, deposition shifts to sediments entrained around the lake edges and transported to the center in suspension. Third, after drainage, further slow mass wasting into the basin accompanies organic accumulation and eolian deposition. Thermokarst sequences may be observed in the headwalls of retrogressive thaw slumps (Burn and Smith, 1990), and, particularly, in coastal exposures (Murton, 1996).

Thermokarst and Climate Change

Thawing of permafrost is a consequence of climate warming (Jorgenson et al., 2006), and deepening of the active layer increases emissions of methane and carbon dioxide due to increased respiration by soil microfauna (Christensen et al., 2004). The widespread climate warming in Arctic regions since the 1980s has been associated with thermokarst development in some areas (Jorgenson et al., 2006; Payette et al., 2004), and, in the past, periods of climate warming have also been periods of thermokarst lake initiation (Burn and Smith, 1990; Rampton, 1988). In western Arctic Canada, the rate of thaw-slump development around tundra lakes almost doubled during 1973–2004 in comparison with 1950–73 (Lantz and Kokelj, 2008). However, as discussed above, initiation of thermokarst features may occur on a site-specific basis, and may follow surface disturbance, irrespective of climate warming. For example, the lakes illustrated in Figure 1 appear to have been initiated at various times during the last 800 years (Burn and Smith, 1990). Furthermore, once a thermokarst basin is filled with water, the thermal regime of the lake bottom is disconnected from climatic conditions by the properties of the water, and thawing of ice-rich permafrost around the lake may proceed regardless of the climate (Mackay, 1978).

The prospect of thermokarst development accelerating during the twenty-first century has been a key factor stimulating research into permafrost conditions, especially with renewed interest in northern hydrocarbon development. Wholesale eradication of permafrost will take many millennia, but the upper layers of the ground appear to exhibit some response to climate warming already, for North America's longest continuous active-layer record, from the Illisarvik field experiment in western Arctic Canada, shows a gradual increase in annual thaw depth from 1983 to 2008 (Burn and Kokelj, 2009). The long-term stability of infrastructure above permafrost is now widely recognized as problematic for northern development projects. There is also widespread concern that acceleration of thermokarst lake development will lead to significant emission of CH_4 from lake sediments (Walter et al., 2006). While there is no doubt that anaerobic decomposition of organic material in lake-bottom sediments commonly leads to release of methane, the relation between aggregate lake expansion and climate change is not yet clear. This is because numerous factors influence shoreline recession, especially the local ground-ice content, and because thermokarst lakes may also drain if the surrounding permafrost no longer encloses them. However, the key observation at present is probably the accelerating initiation of tundra lakes due to degradation of ice wedges, reported from northern Alaska (Jorgenson et al., 2006), which suggests the methane flux from ice-rich tundra regions is probably increasing at present.

Phytoliths

M S Blinnikov, St. Cloud State University, St. Cloud, MN, USA

What Are Phytoliths?

Phytoliths (from Greek *φυτό* *phyto*, 'plant,' and *λίθος* *lithon*, 'stone') are a class of microfossils commonly produced in higher plants (Pearsall and Piperno, 1993; Piperno, 2006). They are composed of the noncrystalline (amorphous) form of hydrogenated silica called opal and are sometimes referred to as 'silica bodies,' 'plant opal,' or 'opaline silica.' Calcium oxalate crystals and starch grains produced by some plants may also be considered phytoliths in the broad sense (Hart and Wallis, 2003) but are not discussed here. Opal phytoliths are commensurate in size with typical plant cells and range from 5 to about 200 μm . They are therefore most commonly found in the silt fraction of sediments (Figure 1). Phytoliths are a valuable proxy for reconstructing past plant communities, especially graminoid-dominated types such as grasslands, semideserts, and tundras. Although phytoliths' taxonomic resolution is lower than that of macrofossils (i.e., rarely to the species level), they may provide subfamily or genus-level information for some families (e.g., Pteridaceae (maidenhair ferns), Pinaceae (pines), Poaceae (grasses), Cyperaceae (sedges), and Asteraceae (asters, daisies, sunflowers)). They also accumulate more locally than pollen and are remarkably durable in dry, acidic, or aerobic conditions (e.g., in paleosols, dung, or cave deposits), where pollen is scarcely preserved (Blinnikov et al., 2002; Piperno, 2006; Strömberg, 2005).

Phytolith Formation

Silicon is the second most common element in the Earth's crust. Phytoliths are formed inside plant tissues from soluble silica carried up by plant vessels from groundwater in the process of transpiration (Raven, 1983). The weathering of silicate minerals such as quartz at the Earth's surface provides large amounts of labile silica, some of which is absorbed by growing plants (Saccone et al., 2007). In solution, silica may exist as monosilicic acid ($\text{Si}(\text{OH}_4)$) when pH values range between 2 and 9. It is carried upward in the vascular system and becomes concentrated because of transpiration around the leaf stomata and in epidermis in general. The supersaturated solution begins to polymerize or gel and then solidifies and forms solid opaline silica ($\text{SiO}_2 \times n\text{H}_2\text{O}$) bodies (phytoliths) within and between some of the plant cells. Although in many plants greater amount of transpiration leads to higher levels of silicification,

the exact relationship between transpiration and deposition of phytoliths remains poorly understood (Piperno, 2006).

The first documented phytoliths (Struve, 1835) were those from grasses, and for many years, these were the most extensively studied (Figure 2; Mulholland, 1989; Smithson, 1958; Twiss et al., 1969). Phytoliths are also described from pteridophytes (ferns), gymnosperms (Klein and Geis, 1978), and selected families of angiosperms (Geis, 1973; Morris et al., 2009), throughout the world. Nevertheless, it should be noted that not all plants produce phytoliths. Piperno (2006) lists about 50 families of higher plants as confirmed phytolith producers as compared to 78 families in which phytoliths have not been observed, despite extensive studies. It is important to note that some of the latter families do accumulate some silica but no observable phytolith morphotypes.

Phytoliths are found in nearly all plant structures: stems, leaves, roots, and inflorescences. In general, many more phytoliths form in the aerial tissue than subterranean tissue probably because of the role played by aboveground evapotranspiration in precipitating silica from solution near the epidermal surface (Figure 3). Patterns of phytolith formation appear to be consistent within families and species from continent to continent (Piperno, 2006); however, only a fraction of the global flora has been investigated for phytolith presence. The formation of phytoliths often involves the filling of the entire cell interior. Cell interiors act as molds, producing casts of solid phytoliths of different repeatable three-dimensional (3D) shapes, more or less corresponding to the cell wall outline. In contrast, the most studied diagnostic phytoliths of grasses and sedges are actually produced inside the cells under an active enzyme control (Blackman, 1969; Sangster et al., 2001) and do not fill the entire cell as in a mold. Such solid phytoliths are denser, more resistant to dissolution, and more durable than those produced by the molding/infilling process. For example, Fraysse et al. (2009) found that an average phytolith of a horsetail or larch has only a 6-year half-life in a soil solution (10–12 years at $\text{pH}=2-3$ to <1 year at $\text{pH}>6$). Grass phytoliths, in contrast, may have half-lives of many hundreds or even thousands of years, especially in dry conditions.

Phytoliths from woody plant species (trees and shrubs) have been much less studied. One reason for this is poor preservation of the most common tree phytoliths (polyhedral and anticlinal epidermal) produced in the cell walls of leaves of these plants. These phytoliths are poorly preserved because of their fragile flat structure with long edges and high surface-to-volume ratios.

Figure 1 Mainly grass phytoliths from late MIS 3 stage sediments (ca. 29 000 years BP) from central Alaska. Lobate trapezoids, cf. *Poa*, are visible from two different angles in A and B. Scale bar is approximately 10 μm .

Figure 2 Polygonal phytoliths from *Quercus macrocarpa* leaf. Scale bar is approximately 10 μm .

Figure 3 Bilobate phytoliths from the leaf epidermis of *Panicum virgatum*, a typical C_4 panicoid grass from the tall grass prairie in the American Midwest. Scale bar is approximately 10 μm .

However, spherical tree phytoliths, produced in large numbers in the center of groups of silicified epidermal cells of trees and shrubs, tend to be better preserved (Bozarth, 1992). These are especially common in the tropical plants and are in fact used in indices diagnostic of specific tropical biomes (Bremond et al., 2005, 2008a,b). Modern collections of tropical phytoliths do exist, but there are fewer well-known diagnostic forms as compared to graminoids (Kealhofer and Piperno, 1998; Runge, 1999).

Phytolith Composition, Characteristics, and Function

Phytoliths are composed of amorphous (noncrystalline) silicon dioxide (SiO_2) and about 4–9% water with admixture of other chemical elements. Measurable amounts of microcrystalline structures have been reported within phytoliths, creating the possibility of direct dating by optically stimulated luminescence (Rowlett and Pearsall, 1993). Phytoliths are optically isotropic, with refractive indices between 1.41 and 1.47 and a specific gravity between 1.5 and 2.3. Under transmitted light, they range from colorless to slightly brown or pink to opaque. The coloration may be related to the presence of iron and other elements as well as to the residual organics and/or exposure to fire (charred carbon). Phytoliths frequently contain significant amounts of occluded, chemisorbed, or solid elements such as aluminum, iron, titanium, manganese, phosphorus, copper, nitrogen, and carbon. It is thought that the presence of carbon within phytoliths is the result of the trapping of plant cellular material during phytolith formation. The presence of carbon allows directed ^{14}C dating of phytoliths (see the Section 'Phytoliths and Chronology'). It has been demonstrated that more than 50% of this encapsulated carbon is protected from oxidation and thus provides another source of paleoenvironmental and paleoclimatic information (Kelly et al., 1991).

Moreover, because phytolith-occluded carbon is of plant cellular origin, it is theoretically possible that deoxyribonucleic acid (DNA) is present and could provide direct evidence of floral origin. Recent attempts at isolating DNA from phytoliths have unfortunately been unsuccessful (Elbaum et al., 2009).

The functional significance of silica in plants is not obvious. In some families, the mechanism of phytolith formation appears passive, and so they represent no more than 'waste products' (Sangster et al., 2001). Alternatively, phytoliths provide mechanical support, preventing the collapse of cell walls under tension during transpiration (Raven, 1983). Moreover, phytoliths provide plants with increased resistance to browsing by herbivorous mammals and insects and attack by pathogenic fungi (Massey et al., 2007; McNaughton et al., 1985).

An interesting observation is that plant families that use organic materials (e.g., cork, lignin) for internal structural support do not accumulate as much silica as families that rely primarily on inorganic material such as silica. Silica is heavy but energetically cheap to absorb from soil and redeposit. In contrast, organic structures must be manufactured by plants internally at a considerable energy cost, but they are more lightweight and versatile. Thus, there must be an evolutionary trade-off between silica 'absorbers' versus silica 'refusers.' In spite of our incomplete understanding as to why some plants prefer silica and some do not, it does appear that silicon is an

essential element in the development of many species (Piperno, 2006; Raven, 1983).

Phytolith Morphology

Phytolith analysis is based on the premise that shapes of phytoliths correspond to the taxonomy of plants in which they formed. In this sense, phytoliths are just another class of microfossils, like pollen. What is different about them, however, is the imprecise correspondence between the shapes of phytoliths and their taxonomic position. Each species produces only one kind of pollen. This is not the case with phytoliths. Each plant produces many different phytoliths, depending on the tissue (multiplicity of shapes). In a thorough study of phytolith production in wild rice (*Zizania palustris*), Yost and Blinnikov (2011) found 23 different morphotypes in *Zizania* that were locally diagnostic of the species. As a rule, only a few morphotypes are abundant within the plant, and in practice, many analysts choose to lump some morphotypes together for faster counts. Still, the sheer diversity of morphotypes, even within a single species, represents the first challenge of the method because there are few comprehensive studies of phytolith production at the species or genus level (Twiss, 2001).

The second, and more serious, challenge is that of redundancy. To understand redundancy, consider pollen: all oaks produce *Quercus*-type pollen diagnostic of the genus, and no other genera produce this type of pollen. Thus, when *Quercus*-type pollen grains are encountered in sediments, they suggest presence of oak. With phytoliths, identical morphotypes can be found in many taxa. For example, all grasses produce flat rectangular epidermal cell phytoliths ('short plates'), which are common across all subfamilies and are thus redundant. Such phytoliths do suggest Poaceae family in a sediment record but provide no information about what subfamily or genus of grasses they may have come from. These two problems (multiplicity and redundancy) make phytolith studies considerably more challenging than pollen analysis and explain why the method has been lagging behind palynology, although phytoliths were first described by botanists around the same time as pollen (Struve, 1835).

Representativeness and Preservation

Phytolith analysis is a rapidly evolving discipline, and there are many basic identification problems to be resolved. Again, these problems are numerous, such as the many different phytoliths that are found in a single taxon, and redundancy, when the same form can occur in many taxa. Yet another problem is associated with lack of representation of some phytolith forms in assemblages extracted from sediments (differential preservation). As mentioned above, some phytoliths produced by plants do not persist for long and are poorly represented in sediments. For example, in a study of sedge and grass phytolith production in Minnesota wetlands, Yost and Blinnikov (2011) discovered that sedges were greatly underrepresented relative to grasses in modern lake sediments. Even in cases where sedges represented over half of all vegetation cover around the lake, more than 90% of identifiable phytoliths in

sediments were those of grasses, and very few sedge phytoliths were encountered in modern samples. Sedges do produce phytoliths, but they are apparently much more fragile forms, prone to rapid dissolution. Cabanes et al. (2011), in a controlled experiment in Israel, proved that modern inflorescence wheat phytolith morphotypes (which are long and fragile dendritic forms) were less stable than those from leaves or stems. Furthermore, burned phytoliths were less stable than unburned, and a fossil phytolith assemblage ca. 3000 years old was more stable than the modern wheat assemblage, due to the removal of the fragile forms over time. The study also showed that individual morphotypes have different stabilities, and as a result of dissolution and abrasion, some morphotypes may resemble others over time. Fishkis et al. (2010) set up an experiment to test downward transport of phytoliths in soil profiles and found that in some soils (Cambisols), addition of water significantly increased vertical movement of phytoliths from <1 to >2 cm. The addition of earthworms, on the other hand, did not substantially increase vertical transport. Clearly, more studies are needed to assess the degree of vertical translocation in soils.

With respect to horizontal translocation, Blinnikov et al. (2011) demonstrated that phytolith assemblages, under control mixtures on 9 × 9-m plots, do in fact reflect specific phytolith producers on these plots after 8 years of experiment. However, a small proportion of phytoliths (<5%) could not be attributed to the producers on the plots themselves and in all likelihood came from neighboring plots a few meters away. Fredlund and Tieszen (1997) found that close to half of all phytoliths in native prairies may be translocated from a few to a few hundred meters away, due to fire, wind, or animal movements, on the scale of hundreds of years.

Despite these problems, many reference collections of modern phytoliths and soil assemblages are being compiled within specific regions. One such example is the reference collection produced by Wallis (2003) who documented the occurrence of distinctive phytoliths from the leaves of 177 non-Poaceae plant species from northwestern Australia. The study showed that although only 50% of the specimens examined were phytolith producers, there was enough morphological variability to distinguish between fossil phytolith assemblages from the region. Blinnikov (2005) documented phytoliths in more than 30 species of most common grasses, forbs, and trees in Oregon and Washington states. Morris et al. (2009) produced a reference collection of grass and nongrass phytoliths for the Great Basin in the United States. Other locations that have seen much research on regional phytolith production have been the Neotropics (Piperno, 1988), Argentina (Fernández Honaine et al., 2009; Gallego and Distel, 2004), South Africa (Cordova and Scott, 2010), west and central Africa (Bremond et al., 2005; Eichhorn et al., 2010; Runge, 1999), the Middle East (Ball et al., 2007), the Russian Caucasus (Blinnikov, 1994), southeast Asia (Kealhofer and Piperno, 1998), China (Lu et al., 2005), and India (Kajale and Eksambekar, 2007).

Terminology and Classification

Historically, the terminology and classification of phytoliths have depended on the researcher. The same basic shape could be variously called a 'hat,' 'conical,' 't-phytolith patelliform,' or

'rondel,' for example. While some researchers only used the geometry of the shape in its name, others gave phytoliths names linked to their presumed anatomical source (e.g., tracheid, epidermal cell, trichome). To make things even more complicated, only fairly recently did researchers begin to use true 3D shapes in phytolith analysis, as seen under rotation in a liquid medium (Figure 4). Much of the research done in the 1960s through 1980s relied primarily on fixed media for phytolith counts, making some shapes impossible to identify correctly. For example, bilobate and some trapezoidal lobate forms may appear identical in certain orientations but completely different in others (Rapp and Mulholland, 1992).

The main reason for this overall confusion is the genuine problem of continuity of shapes exhibited by phytoliths and the lack of exact 'types,' unlike in pollen or diatom analysis. A number of independent schemes were devised which were used to deal with phytoliths extracted from plants or sediments, generally from a specific region. There was a certain amount of overlap between these schemes, and over the years, a number of attempts have been made to develop a universally accepted standard classification scheme (Bowdery et al., 2001; Pearsall, 2000). In order to establish standards and to harmonize the naming and description of phytoliths, a working group has been formed that has developed a standard protocol for naming phytolith types and a glossary of descriptors: *'The first International Code for Phytolith Nomenclature 1.0'* (Madella et al., 2005). It is suggested that when naming a particular phytolith type, there should be up to three descriptors. The first descriptor should be for the 2D or 3D shape. The second descriptor should be texture and/or ornamentation and should be added if they are characteristic or diagnostic. A third descriptor can be added when the anatomical origin is clear and beyond doubt. For example, bulliform is an established botanical term used to describe a particular type of cell found in grass leaf epidermis. In this particular case, the word conveys both an anatomical and a descriptive meaning. It is expected that as the scheme is adopted, it would undergo a number of changes, as more phytoliths are discovered and described (Table 1).

An alternative solution would be to abolish typological approach entirely and rely on some image recognition protocol that could automate phytolith shape and size counts for certain projects where only few basic forms are observed (Ball et al., 1996). Computer image recognition software may assist in quickly estimating proportion of certain shapes and sizes on the cover slip and then assign probability of each sample belonging to a particular standard from a specific plant community. However, most analysts work with true 3D shapes of phytoliths and rotate grains under the microscope, while typical image recognition software can only work in 2D, so much more research in this area is necessary.

Phytolith Analytical Techniques

Phytoliths are composed of opal, that is, hydrated non-crystalline silica, a material extremely resistant to acids and high temperatures (up to 1000 °C), but soluble in very alkaline solutions and mildly soluble in water if immersed for long intervals. Opal is significantly less dense than quartz (1.5–2.3 vs. 2.6 specific gravity, respectively). Therefore, extraction of

phytoliths from plants and sediments relies on either heat (ashing in a muffle furnace) or strong acidic digestions (e.g., with hot concentrated nitric acid) to remove organic matter. Additional treatments include mild hydrochloric acid to remove carbonates and flotation in heavy liquid (e.g., solutions of zinc iodide, sodium polytungstate, or toluene, usually at 2.3 specific gravity) to separate phytoliths (<2.3) from heavier minerals (e.g., quartz is about 2.6). The techniques of phytolith extraction are basically the same as those of diatom extraction. One of the challenges of working with aquatic sediments is precisely in separating phytoliths from diatoms, with the latter commonly outnumbering similarly composed phytoliths by 10:1. Although both are made from the same biogenic silica, the fine difference in shape and density, and therefore buoyancy, may allow separation of most common short cell phytoliths of grasses (compact and dense) from most common diatoms (usually more elongated and less dense; Yost and Blinnikov, 2011).

For a full range of suitable phytolith field techniques, research design, laboratory analytical methods, and techniques, as well as interpretation methods and theory, refer to Piperno (1988, 2006) and Pearsall (2000). Parr (2002) described an alternative microwave digestion technique for extracting phytoliths from sediments. The technique has obvious advantages in reducing the preparation time for phytolith analysis, as well as reducing the chance of contamination, by reducing the number of steps involved. For example, the traditional technique of acid digestion requires 6–8 h. Microwave digestion may take only an hour.

Advances in scanning electron microscopy (SEM) allow very accurate images of phytoliths to be obtained. However, most phytolith analysts prefer to rely on traditional optical microscopes for counting shapes, for faster and cheaper processing. Additionally, standard SEM images are static and do not allow for easy 3D rotation. Nevertheless, with the advent of digital photography, even optical microscopy can now provide reliable high-quality images, including both stills and videos. For fine analysis of surface sculpturing and other close-up details, SEM is the tool of choice. However, few of the details visible in SEM images appear to be diagnostic.

Phytoliths and Chronology

Radiocarbon

An important aspect of late Quaternary research has been the ability to reliably date changes in the relevant sequences and processes. In addition to providing vegetation information, phytoliths contain datable ¹⁴C. Moreover, because phytolith-occluded carbon is effectively sealed against postdeposition contamination at the time of the phytolith formation, they provide an ideal time capsule for use in radiocarbon dating. Wilding (1967) was the first to determine a radiocarbon age from phytolith-occluded carbon. However, because of the large samples (45 kg of sediment) needed prior to the advent of accelerator mass spectrometry (AMS) dating, it was not practical to replicate his study. Following the development of the AMS dating method (requiring far smaller samples) in the late 1970s, more radiocarbon dates have been obtained from phytoliths (Mulholland and Prior, 1993). As with most new techniques, issues have been raised with regard to preparation, accuracy, and reliability, and more research developments are expected.

Optically Stimulated Luminescence

In spite of being generally described as amorphous, phytoliths appear to contain microcrystal structures. Theoretically, these microcrystal structures should be able to trap electrons and, as such, offer potential material for thermoluminescence (TL) dating. Rowlett and Pearsall (1993) examined the feasibility of TL analysis of phytoliths. They dated a number of phytoliths from sediments associated with ceramics of known cultural affiliation and radiocarbon-dated organic material. However, although their TL dates were in general agreement with the previously

accepted ages, indicating the potential of this method, the phytolith matrix was shown to be unstable at high temperatures.

Phytolith Chemical Analysis

In recent years, previously unstudied chemical components of phytoliths and their occlusions have been analyzed and documented, following the development of new instruments and techniques. Instruments such as the inductively coupled plasma source mass spectroscope, capable of measuring elements in parts per billion, have opened up the possibility of measuring trace elements present in minute quantities in phytoliths. Hart (2001) used this technique to examine trace elements present within phytoliths from the leaves of *Actinotus helianthi* and *Triodia mitchellii*. She was able to confirm the presence of more than double the previously documented number of phytolith-occluded trace elements. Smith and Anderson (2001) used tetramethylammonium hydroxide (TMAH) thermochemolysis and gas chromatography–mass spectrometry (GC–MS) to characterize the organic compounds in C₃ and C₄ phytoliths.

In an attempt to improve on phytolith taxonomic resolution, Carnelli et al. (2002) have proposed a new method of distinguishing between similar morphological forms from different taxa. Using X-ray analysis paired with phytolith morphology, they have been able to demonstrate that aluminum in phytoliths from Ericaceae (heaths) and conifers was found in significantly higher concentrations than in those from Cyperaceae and Poaceae. The technique will require further investigations of different taxa to confirm that the codeposition of aluminum and silicon in phytoliths is more frequent in woody plants than herbaceous plants.

Stable Isotope Analysis

It has been demonstrated that the stable isotope analysis of phytoliths can contribute considerable paleoenvironmental and paleoclimate evidence (Kelly et al., 1991; Smith and Anderson, 2001; Smith and White, 2004; Webb and Longstaffe, 2003). Tests carried out by Kelly et al. (1991) confirmed that the carbon occluded within phytoliths is protected by the nonporous glasslike microstructure of the silica body and is therefore unlikely to be vulnerable to decay.

Information about climatic conditions during plant growth may be inferred from the $\delta^{18}\text{O}$ signature preserved in oxygen isotopes from phytoliths, as discussed by Webb and Longstaffe (2003). Their hypothesis was that climate factors which affect the isotopic composition of oxygen of water (H₂O) within growing plants should leave a record in the oxygen isotopic ratios of phytolith silica. They were able to determine that the plant growing temperature is recorded in the $\delta^{18}\text{O}$ of phytoliths formed within the nontranspiring tissue of grasses. However, the signal from nontranspiring tissue can be masked by phytoliths from transpiring tissue, which in contrast are variably enriched in $\delta^{18}\text{O}$, depending on relative humidity.

Phytoliths trap trace amounts of organic carbon (0.09–1.3 wt%; Kelly et al., 1991). Organic compounds can be attached to the silicates by hydrogen bonding, or alternatively parts of the cytoplasm may become occluded within the phytolith as they silicify (Fredlund, 1993). Wilding's (1967) isolation and radiocarbon analysis of phytolith carbon created the

opportunity to extract more paleoenvironmental information. Fredlund (1993) demonstrated that careful analysis of phytolith-occluded carbon had the potential to reconstruct record of the range, variability, and changes of C_3 (around 27‰ $\delta^{13}C$) and C_4 grasses (around 12‰ $\delta^{13}C$) of past grassland ecosystems. However, Smith and Anderson (2001) showed that the method was limited by the compression of the phytolith $\delta^{13}C$ scale (6.6‰) relative to the whole plant scale (11.2‰). Their study demonstrated that it was possible to characterize the phytolith organic compounds in C_3 and C_4 grass phytoliths using TMAH and GC-MS analysis. These analyses record the presence of lipids, which are generally depleted in $\delta^{13}C$, and suggested, therefore, that lipid presence explains the depletion in $\delta^{13}C$ in phytolith carbon, relative to whole plant $\delta^{13}C$. Moreover, they suggested that the isotopic differences in C_3 and C_4 grass phytoliths were most likely caused by differential fractionation associated with the formation of lipids in C_3 and C_4 plants. Smith and White (2004) have gone on to resolve some modern calibration issues raised in previous work and show that the carbon isotope ratios of fossil phytoliths present a unique tool for reconstructing the proportion of C_3 and C_4 grasses in ancient grasslands.

The occluded carbon within phytoliths is formed by photosynthesis from atmospheric CO_2 when the plant was growing. Therefore, it should be possible to relate the carbon isotope analysis of phytolith-occluded carbon with carbon isotope concentration in atmospheric CO_2 . Carter (2009) has extracted a last glacial cycle record from phytoliths extracted from a 120 000-year-old loess sediment core. Phytoliths were extracted from the 7.4-m core, and the occluded carbon was analyzed morphologically and isotopically. Rates of isotopic fractionation between plant and phytolith were determined by measurements from a number of modern tree, fern, and grass species. There was little correlation between the $\delta^{13}C$ record and the phytolith morphological assemblages, suggesting that the $\delta^{13}C$ signal from occluded carbon was largely determined by the atmospheric CO_2 carbon isotopic ratio.

Although stable isotope studies of phytoliths show promise, Webb and Longstaffe (2010) have not found a significant correlation ($r < 0.3$) between climate variables and the $\delta^{13}C$ values of *Calamovilfa longifolia* tissues (average $\delta^{13}C = -13.1 \pm 0.6$ ‰; $n = 70$) in a robust study across the North American prairies. The strongest correlations were obtained between the $\delta^{13}C$ values of stem or sheath phytoliths and humidity ($r = 0.3$), latitude ($r = 0.4$), and amount of precipitation ($r = 0.5$). However, use of these relationships was limited by the wide spread in $\delta^{13}C$ values of phytoliths from different plant tissues at the same location.

Paleoenvironmental Reconstruction Using Phytolith Analysis

Some of the earliest known phytoliths come from the time of dinosaurs in the late Cretaceous, dated about 80 million years BP (Prasad et al., 2005). Already at that time, shapes attributable to modern subfamilies of grasses could be detected. Phytolith research in the Miocene (Strömberg, 2005) demonstrated the high utility of the method when applied to times of rapid grass evolution, coupled with strong environmental change. In Pleistocene records, phytoliths allow analysis of

long records, particularly from loess (Blinnikov et al., 2002; Lu et al., 2005) that span over 100 000 years and potentially the entire 2.6 million years of the epoch. Analysis of paleosols, lake sediments, cave deposits, and animal middens allows the application of phytoliths to focus on the most dramatic times of climate change, such as the Last Glacial Maximum and Late Glacial to interglacial transition, as well as short-term fluctuations such as the Younger Dryas oscillation and events in the mid-Holocene.

Because of the lack of clear ‘types’ and high redundancy of many forms, it is best to combine phytolith analysis with other proxy studies, such as macrofossils, pollen, chironomids, and paleogenetic methods, done on the same sediments using a multiproxy approach (Blinnikov et al., 2002; Cordova et al., 2010; Wooller et al., 2011).

There are a few common approaches to interpreting phytolith paleorecords. They include (a) detection of specific, highly diagnostic forms in order to infer presence or absence of a specific taxon (Yost and Blinnikov, 2011); (b) matching modern and paleoassemblages to interpret paleovegetation (Blinnikov et al., 2002); (c) matching modern and paleoassemblages to infer paleoclimate via a transfer function; or (d) looking for changes in ratios of different plant functional groups (e.g., trees vs. grass) as interpreted on the basis of an index of different morphotypes (Bremond et al., 2008a,b).

An example of the direct diagnostic match is that of Yost (2007), who studied wild rice in Minnesota lakes. He was able to demonstrate the existence of wild rice in Lake Ogechie as early as 3500 years BP, based on highly diagnostic rondels from the wild rice inflorescence, considerably earlier than previously inferred from pollen (2500 years BP).

Bremond et al. (2005, 2008a,b) proposed and tested a few indices that allowed interpretation of paleovegetation in Africa, based on ratios of nonarboreal and arboreal forms. Fredlund and Tieszen (1994, 1997) developed a robust modern dataset that allows direct matching of any paleosols from the Great Plains in North America to their modern analogs, both in terms of climate and vegetation type. Cordova et al. (2010) and Morris et al. (2009) tested the applicability of a burned phytolith index, a ratio of charred versus clean phytoliths, as a proxy for paleofires that can complement charcoal records.

Many paleoenvironmental reconstructions involving phytolith analysis have used qualitative or quantitative methods and a combination of the above-listed approaches (Powers-Jones and Padmore, 1993). For example, Carter and Lian (2000) used the morphological differences in phytolith assemblages extracted from a well-dated 6.4-m loess sediment core to infer changes in the relative abundance of forest versus grass cover. The record showed correlations between the tree-shrub phytolith fluctuations and the oxygen isotope curve between marine oxygen isotope stages (MISs) 1 and 5, suggesting that changes in the ratio of arboreal to nonarboreal phytoliths directly result from changes in climate (Figure 5).

Since 2000, more rigorous statistical and image analysis methods have been employed to provide better statistical procedures, dating techniques, and analytical methods. For example, in order to establish a more quantifiable relationship between vegetation and phytolith assemblages, various quantitative statistical methods have been applied, such as

Figure 5 Example of a phytolith stratigraphic frequency diagram showing vegetation changes through time from southeastern North Island, New Zealand. ka, thousand years before present. Reprinted from [Carter JA and Lian OB \(2000\)](#). Paleoenvironmental reconstruction from the last interglacial using phytolith analysis, south eastern North Island, New Zealand. *Journal of Quaternary Science* 15: 733–743, with permission.

constrained classification techniques and cluster analysis and correspondence analysis (see review in [Piperno, 2006](#)). [Bobrov et al. \(2001\)](#) used cluster and canonical correspondence techniques to distinguish among the phytoliths from 69 Cyperaceae and Poaceae species. A transfer function technique used by [Prebble et al. \(2002\)](#) quantified the relationship between modern phytolith assemblages and environmental parameters for the quantification of a long late Quaternary paleoenvironmental record. [Blinnikov et al. \(2002\)](#) used a squared chord distance dissimilarity measure to successfully match modern and paleoassemblages for eight common vegetation types of the Pacific Northwest. For example, their study showed that it was possible to distinguish a ponderosa pine-dominated forest from a Douglas-fir-dominated forest or mesic *Agropyron*–*Festuca* grassland from xeric *Stipa*–*Poa*-dominated grassland. They also attempted direct interpretations of paleoclimate parameters based on their modern phytolith dataset. However, the range of modern climates from the region was not sufficiently broadly tested to distinguish much paleoclimatic diversity. Part of the problem was the necessary concentration of modern sample sites in only the few modern grasslands in the region, not fully representative of the modern climate range. Another

problem was an inability to match nonanalog paleoclimates of the late Pleistocene. [Bremond et al. \(2008a\)](#) demonstrated high precision of phytoliths in correctly detecting four key biomes in west Africa. In their study, phytoliths outperformed pollen in detecting regional biomes ([Figure 6](#)).

Phytoliths in Archaeological Research

The study of the Quaternary inevitably touches on human history, and many methods are employed in common in archaeology-, anthropology-, and geology-based Quaternary research. As the climate warmed following the last glacial interval, ca. 12 ka BP, humans began experiments in cultivating wild grasses, leading to the development of agriculture. Distinctive phytoliths have been described from wheat (*Triticum* spp.), barley (*Hordeum* spp.), millet (*Panicum* spp.), rice (*Oryza sativa*), maize (*Zea mays*), and wild rice (*Zizania palustris*). Other families that produce phytoliths important in archaeological research include bananas (Musaceae), squashes (Cucurbitaceae), euphorbias (Euphorbiaceae), bromeliads (Bromeliaceae), and dayflowers (Commelinaceae). Presence of these and other phytoliths in ancient sedimentary deposits

Figure 6 Assignment of the samples to (a) pollen and (b) phytolith biomes (Bremond et al., 2008a,b). (c) Olson's ecosystem classes (16 in this study area) were combined and reduced to seven groups representing more than 94% of the area. Reprinted from Bremond L, Alexandre A, Peyron O, and Guiot J (2008) Definition of grassland biomes from phytoliths in West Africa. *Journal of Biogeography* 35: 2039–2048, with permission.

has been used as evidence for the development of agriculture and landscape change in several independent centers, including North and South America, the Middle East, and south and southeast Asia. Accordingly, phytolith analysis is used extensively in archaeology, with particular respect to the early exploitation and development of grain crops (Meunier and Colin, 2001). Asian rice (*Oryza sativa* L. var. *japonica*) was domesticated in the middle Yangtze River Valley of southern China shortly after the termination of the Pleistocene. Distinctive morphological differences between phytoliths found in wild and domesticated *Oryza* species are particularly suitable in documenting change from early exploitation of a wild resource to its subsequent cultivation (Zhao and Piperno, 2000).

Analysis of phytoliths from sediments has also proved useful in describing the early cultivation of nongrain crops such as banana and taro. Hybridization of varieties of banana and of taro has resulted in near-sterile plants, producing little or no seed. However, these plants still produce distinctive phytoliths and starch, which have been extracted from prehistoric sediments and used to document the deliberate planting of taro (*Colocasia esculenta*) and banana (*Musa* spp.). This demonstrates that agriculture arose independently in New Guinea between 6950 and 6440 years BP (Denham et al., 2003). One

of the more interesting questions regarding the domestication of banana is how and when it got to Africa. No wild bananas have ever been reported in the natural state in Africa; therefore, they must have been deliberately introduced by humans. *Musa* phytoliths, dated from the first millennium BC, from an archaeological site in South Cameroon, document the first recorded presence of domesticated *Musa* bananas in central Africa (Mbida et al., 2000).

Plant Macrofossil Introduction

H H Birks, University of Bergen, Bergen, Norway

© 2013 Elsevier B.V. All rights reserved.

This article is reproduced from the previous edition, volume 3, pp. 2266–2288, © 2007, Elsevier B.V.

Introduction

Plant macrofossil analysis is being increasingly used in Quaternary science. Quantitative paleoecological macrofossil analysis was developed by W.A. Watts in the United States (Birks and Birks, 1980; Watts and Winter, 1966) and his work showed the value of combining macrofossils with pollen analysis. Macrofossil analysis is a 'low-tech' process, but it requires patience and a good botanical knowledge of plant identification and ecology. This subsection describes the up-to-date developments in macrofossil analysis and illustrates how diverse its uses and applications have become. It has become an essential tool in paleoecological studies and, of course, has long been the foundation of paleoethnobotany and archaeobotany. This article is intended to provide a background and a survey of the uses of plant macrofossil analysis as presented in the literature. Further background information is available from the list of works found in the References section.

What Is a Plant Macrofossil?

A plant macrofossil can be considered to be a plant fossil that is visible to the naked eye and that can be manipulated by hand. The sizes of macrofossils range from 0.5 mm to enormous tree trunks (usually termed 'megafossils'). The median size is 0.5–2.0 mm. Macrofossils are usually studied using a stereomicroscope at magnifications between 10× and 40×. Greater magnifications (e.g., 100×) can be obtained using a high-power microscope.

Plant remains are not only fruits and seeds but also vegetative parts, such as leaves, cuticles, buds, bud scales, anthers, flower parts, rhizomes, twigs, wood, bark, etc. Lower-plant remains include sporangia and megaspores, mosses (but seldom liverworts, as they are usually not preserved), occasionally lichens and seaweeds, and *Characeae* oospores. During plant macrofossil analysis, animal remains are frequently found, especially in lake sediments (e.g., chironomids, *Cladocera ephippia*, bryozoa, oribatida, Trichoptera, and fish). Quaternary plant macrofossils are seldom true fossils where the organic material is replaced by inorganic minerals. They are most often the original organic material and thus can be termed subfossils.

Occasionally, the remains are trace fossils, for example, impressions in sediments or 'negative' impressions in pottery.

Why Study Plant Macrofossils?

What Can Plant Macrofossils Add to a Paleoecological Study?

Macrofossils are often studied in conjunction with pollen and add new dimensions to pollen studies.

- Macroremains can often be identified to a higher taxonomic resolution than pollen, often to species level.
- Macroremains can be recovered of taxa that produce little or no pollen, including cryptograms.
- Macroremains are relatively heavy and are generally not dispersed far from the parent plant. Exceptionally, streams and rivers may transport remains far from their source, and winter winds can disperse seeds and fruits many kilometers over a smooth winter-snow surface. These processes aid dispersal and colonization of recently deglaciated landscapes. In the Arctic, they have contributed to the formation of the relatively uniform circumarctic flora. However, most plant remains are deposited near their sources, which allows past local vegetation to be reconstructed in some detail.
- When local pollen production is sparse, the pollen signal may be confused by the relatively large amounts of pollen that have been transported from great distances. In such situations, plant macrofossils are needed to provide realistic reconstructions of the local vegetation (see Birks and Birks, 2000, 2003).

Where Are Macrofossils Found?

Being organic, plant remains are found only in places where decay is inhibited, usually in anoxic, waterlogged, arid, or sometimes frozen environments. They are best preserved in low-energy environments because of their delicate nature.

Macrofossils are most often studied from lake or peat sediments. Sequential deposition means that temporal series can be analyzed. Rapid accumulation can result in finely detailed sequences showing changes in vegetation and environment

(e.g., Birks, 2000; Birks et al., 2000). Mire communities produce peat *in situ*, and the plant remains thus reflect the local peat-forming vegetation. Fruits and seeds can be sparse in peat deposits, especially bog peat, and thus the identification and quantification of vegetative parts and mosses, including *Sphagnum*, play an important role. Macrofossils in lake sediments also reflect local vegetation but the assemblages also contain remains from neighboring communities, such as littoral swamps and nearby upland vegetation, especially trees (e.g., Eide et al., 2006). Remains can be transported into lakes by wind, birds, inflowing streams, solifluction, and slope-wash (an extreme example is avalanches; Figure 1; Birks, 2001).

Figure 1 Illustration of the taphonomic processes leading to the preservation of macrofossil assemblages in different sedimentary environments. Top: A temperate lake (reproduced from Birks HH (1980) Plant macrofossils in Quaternary lake sediments. *Archiv für Hydrobiologie* 15: 1–60). Middle: An arctic or alpine lake (reproduced from Birks HH (1991) Holocene vegetation history and climatic change in west Spitsbergen – Plant macrofossils from Skardtjørna, an arctic lake. *The Holocene* 1: 209–218). Bottom: A bog or fen. Reproduced from Birks HH (2001) Plant macrofossils. In: Smol JP, Birks HJB, and Last WM (eds.) *Tracking Environmental Change Using Lake Sediments. Terrestrial, Algal, and Siliceous Indicators*, vol. 3, pp. 49–74, Figure 2, © Kluwer Academic Publishers, Dordrecht, The Netherlands, with kind permission of Springer Science and Business Media.

Elsewhere, plant remains are usually deposited as single events. Plant macrofossils can be recovered from soils, and they may contribute to seed-bank studies. Old soils can be preserved by permafrost, and long sequences may be built up by loess deposition. Complete vegetation can be preserved under volcanic ash (e.g., Baales et al., 2002). About 18 000 years ago, arctic tundra was preserved under tephra in the Seward Peninsula, Alaska. Most soft parts disappeared before permafrost penetrated the ash layer, so seeds and fruits, some vegetative remains, and mosses were the major sources of evidence for a local vegetation mosaic determined by moisture availability and snow lie (Goetcheus and Birks, 2001). Preservation in tufa can likewise reflect local vegetation.

Alluvial sediments can be productive sources of plant macrofossils. Macrofossils from Holocene alluvial deposits allowed Baker and colleagues (this encyclopedia) to reconstruct riverine and upland plant communities within the forest and prairie biomes that are poorly differentiated by pollen. Outwash plains of glacial rivers contain organic deposits laid down in calm backwaters, which are subsequently buried (e.g., Holyoak, 1984). The organic lenses in glaciofluvial deposits are important sources of Pleistocene vegetation history. In embayments of forest streams, tree leaves may be well preserved (e.g., Chaney, 1924). Leaf layers may also be preserved in lake sediments, both temperate (e.g., Spicer, 1989) and glacial (e.g., Kråkenes Lake; Gulliksen et al., 1998).

Another source of macrofossil material is archaeological excavations (See Use in Environmental Archaeology). Knowledge of the taphonomy of the samples can yield important information on the lifestyle and economy of past human populations. Samples can be preserved by water logging, such as in wells, latrines, and ditches, and by high water tables in lakeshore dwellings (e.g., in Switzerland) and seashore buildings (e.g., Medieval Bryggen in Bergen; Krzywinski and Soltevedt, 1988). Dry environments preserve samples associated with dwellings (e.g., middens, post holes, hearths, tombs, etc.). Carbonized remains are preserved by their conversion to charcoal. Pottery can contain negative impressions of plant remains that were incorporated in the clay and subsequently incinerated.

An unusual source of plant macrofossils is bodies preserved in peat bogs (e.g., Tollund Man in Denmark, Glob, 1971; Lindow Man in England, Stead et al., 1986), in permafrost (e.g., in Siberia and Alaska), and in ice (e.g., The Italian Ice Man). Frozen corpses of large grazing mammals from full-glacial times have been widely studied from Siberia (e.g., Ukraintseva, 1993) and Alaska (e.g., Zazula et al., 2003). Their diet, reconstructed from stomach contents and dung, reflects the full-glacial vegetation and the nature of the so-called Mammoth Steppe. Analyses of extinct ground-sloth dung from a cave in Patagonia, Argentina, revealed the character of the glacial vegetation before trees arrived in the Holocene (Moore, 1978).

How Do We Sample Plant Macrofossils?

Most lake and bog sediments are sampled by coring. As a larger quantity of sediment is required for macrofossil analysis than for pollen analysis, wide-diameter cores are preferred. With wide cores, high-resolution sampling is possible. Monoliths or spot samples can be excavated from open sections in dry bogs, alluvial

banks, glacial gravel deposits, and archaeological contexts. The monoliths or samples are subsampled in the laboratory or screened on site. All sediments should be refrigerated at 4 °C until required or air- or freeze-dried. For accelerator mass spectrometry (AMS) radiocarbon dating, it is best to dry or deep freeze the samples at –20 °C to prevent microorganism metabolism.

How Do We Do Plant Macrofossil Analysis?

The whole process of macrofossil analyses is summarized in [Figure 2](#) (Birks, 2001). After the material is obtained from the field, subsamples are taken depending on the abundance of

macrofossils and the resolution required. Subsamples for quantitative analysis are ideally about 50 cm³. However, samples of ~25 cm³ or less have been successfully used when the amount of available material is small. The subsamples are stored as above until needed.

For quantitative analyses, subsample volume is measured by displacement of water. Sometimes, weight may be used for the dry sediment. Sediments may need to be disaggregated. Sodium pyrophosphate (Na₄P₂O₇ · 10H₂O) is useful for disaggregating clay-rich samples. Sometimes, gyttja needs to be soaked for a short time (1–2 h) in 10% potassium hydroxide. Calcareous samples can be treated with dilute acid. Archaeological samples can undergo various treatments.

Figure 2 Flowchart showing the processes in a plant macrofossil study. The central column shows the successive phases from sampling to the reconstruction of paleoenvironment and climate. The equipment and information needed are shown on the right. The potential sources of error are shown on the left. Modified from Wasylkova K (1986) Analysis of fossil fruits and seeds. In: Berglund BE (ed.) *Handbook of Holocene Palaeoecology and Palaeohydrology*, pp. 571–590. Chichester: Wiley by Birks HH (2001) Plant macrofossils. In: Smol JP, Birks HJB, and Last WM (eds.) *Tracking Environmental Change Using Lake Sediments. Vol. 3: Terrestrial, Algal, and Siliceous Indicators*, pp. 49–74, Figure 1, © Kluwer Academic Publishers, Dordrecht, The Netherlands, with kind permission of Springer Science and Business Media.

The sample is washed through sieves with a gentle spray of water. Sieves can be stacked if necessary, but the smallest mesh diameter should be about 125 μm if tiny seeds are to be collected. The residue is washed gently off the sieve into a container and kept cold until analyzed. Small quantities of the residue are suspended in 2–3 mm of water in a shallow dish (e.g., Petri dish) and examined systematically under a stereomicroscope at about $12\times$ magnification until the whole sample has been examined. Remains of interest are picked out and sorted, identified, counted, and tabulated.

Results may be presented as lists with presence/absence or numbers, as spots indicating abundance next to the appropriate pollen taxon on a pollen diagram from the same core, or as stratigraphic concentration diagrams (number in a constant volume of sediment calculated from the numbers counted in known sediment volumes). Influx values can be calculated if the sediment accumulation rate is known, but this is rarely done. Normally, percentage diagrams are not used, as there is no consistent 'macrofossil rain' comparable to 'pollen rain,' but they have proved useful in several cases. TILIA.GRAPH has proved to be an excellent computer tool for drawing stratigraphic macrofossil diagrams (<http://www.demeter.museum.state.il.us/pub/grimm>). The program C2 is ideal for plotting various proxies from the same or different cores together.

Identification of Macrofossils

A comprehensive reference collection is necessary for macrofossil identification. For material collected in the field, voucher plant specimens should be made for taxonomically difficult taxa. Alternatively, material may be collected from herbaria. Herbarium specimens are usually collected in flower and may not have seeds present, but they can provide vegetative material. Botanic garden seed exchanges can provide useful material whose provenance is known. Seed banks such as the Kew Millennium Seed Bank and the US Department of Agriculture can also provide material. All items in a reference collection should be numbered and cataloged.

Published photographs and drawings are useful for narrowing down an identification before consulting the reference collection. There are illustrated seed atlases and articles about single genera (see also Birks, 2001). A selection of modern seeds, fruits, and other parts that are often found fossilized or that have proved to be important indicators in macrofossil studies has been photographed for this article (Figures 3–13).

Fossils and reference material are compared under a stereomicroscope. Higher magnification with transmitted or overhead light or a combination of both can reveal cell patterns and other small details. Scanning electron micrographs can be taken, but this is usually impractical for routine identification. Modern material can be 'fossilized' by soaking or heating in 10% potassium hydroxide to remove waxes, fleshy tissue, etc. that normally disappear in sediments. Seed surfaces can usefully be examined while they are drying out; damp or dry surfaces often reveal patterns invisible in wet specimens. Identifications can be easily recorded photographically with the digital equipment now available for both stereo- and high-powered microscopes.

How Do We Interpret Plant Macrofossil Data?

The occurrence of a taxon in an assemblage can be interpreted in terms of its modern ecological tolerances, using it as an indicator species. This approach is used in paleoecology and also in archaeobotany where plant remains are associated with human activity rather than natural vegetation. Assemblages can be interpreted as analogs with modern vegetation and environment, which can strengthen interpretations made from single taxa (Birks and Birks, 1980).

In a quantitative analysis, how can we interpret quantitative changes in the abundance of taxa? A macrofossil assemblage, however local, is derived from vegetation at different scales. Its composition depends on the processes of production, dispersal, deposition (including sorting and redeposition), and preservation (Figure 14). Seed or fruit dispersal mechanism may be unspecialized, but most plants have adaptations that aid dispersal: wings and parachutes for wind dispersal, burrs and reversed spines for external animal dispersal, succulent parts for internal animal dispersal, and corky tissue or small seeds with reticulate patterns that trap air for water dispersal. In reality, many processes may influence seed/fruit dispersal, as well as the apparent adaptation; for example, many propagules float. Distribution of plant remains may be affected by stream or river dynamics, sheet-wash, storms, fires, and smooth snow or ice in winter facilitating wind dispersal. Animal dispersal is influenced by foraging behavior and food preference (e.g., packrats and humans). The arrival of plant remains in a deposit is largely by chance, as few such places are suitable for germination and seedling establishment. Subsequent preservation depends partly on the deposition environment (waterlogged and anoxic, dry, acid, or alkaline) and partly on the structure and composition of the potential macrofossil. Some seeds and fruits are rarely found fossilized, even though they were abundantly produced. A most frustrating example is *Artemisia* fruits. Alternatively, some remains can be superabundant, for example *Juncus* seeds and *Characeae* oospores. This kind of huge imbalance makes the calculation of percentages rather meaningless in most situations.

Taphonomic processes result in a fossil assemblage in which the abundance of the fossils is related somehow to their abundance in the vegetation (Figure 14). Each taphonomic process can be studied independently. However, the pragmatic approach integrates all the processes and relates the fossil assemblages to modern assemblages through modern surface samples. A series of surface samples will indicate the variability of assemblages produced by a vegetation type due to the variability in taphonomic processes.

It is not feasible to relate macrofossil assemblages precisely to modern plant occurrences and abundances, but general relationships can be established (e.g., Birks, 1973). Although macrofossils can be counted or their abundance estimated and stratigraphic diagrams plotted, the actual values are rarely considered as a quantitative representation of the parent vegetation. Gradually increasing knowledge about the representation of plant remains in different depositional environments allows us to estimate in general terms the abundance of taxa in the past and to relate this to modern situations (Birks, 1973).

Scale lines are 1 mm.

Taphonomic processes in the formation of a macrofossil assemblage

Figure 14 The taphonomic processes involved in the formation of a plant macrofossil assemblage. Each process can be studied individually, or the resulting assemblage can be studied using surface samples relating the assemblage to the modern vegetation.

Plant Macrofossils in Paleocology

Plant macrofossil analysis is rarely conducted in isolation. It is usually combined with pollen analysis, and it can profitably contribute to multiproxy studies. A combination of pollen and macrofossil analyses provides more detailed and realistic interpretations than either alone, each filling gaps left by the other. The articles in this 'macrofossil' subsection provide overviews of the value of macrofossils in vegetation history, in some paleoecological situations where pollen evidence is particularly uninformative, and in other Quaternary applications.

Macrofossils in Vegetation History

Macrofossils are important in the study of vegetation history because they can indicate the local occurrence of taxa with abundant, widely dispersed pollen, such as *Betula* and *Pinus* (Birks and Birks, 2000, 2003). This information could have climatic implications (Birks and Birks, 2003). The identification of bud scales provides records of some deciduous trees (e.g., *Quercus*, *Ulmus*, *Corylus*, *Ostrya/Carpinus*) that otherwise produce few macrofossils (e.g., Eide et al., 2006). Some trees and herbs produce small quantities of fragile or nondescript pollen. Macrofossils can provide more detailed paleoecological records (e.g., *Larix*, *Populus*, Cupressaceae, *Juncus*, *Dryas*, etc.). In addition, macrofossils can frequently distinguish taxa below the level of pollen taxa which are typically identified to the family or genus level. Thus they can provide greater detail about forest and other vegetational successions. For example, many conifer needles can be distinguished to species (e.g., Dunwiddie, 1987; Watts, 1979). *Betula* fruits and catkin scales distinguish dwarf from tree birch and between many tree-birch species. Many Cyperaceae can be identified to species (Figure 10) as well as members of the Poaceae, Caryophyllaceae, Ericaceae, Rosaceae, Saxifragaceae, Apiaceae, Potamogetonaceae, Polygonaceae, Juncaceae, and others (see Figures 3–13). The combination of macrofossil and pollen studies of vegetation history and successions, both aquatic and terrestrial, provides much more information than provided by pollen analysis alone (e.g., Eide et al., 2006).

Situations Where Pollen Is Uninformative

Macrofossils can provide paleoecological insight where pollen alone is uninformative or confusing. Most obvious are treeless situations, such as arctic or alpine tundra vegetation or prairie or steppe grassland. The local pollen production of arctic and alpine tundra vegetation is low. Large amounts of long-distance tree pollen can confuse the local vegetation signal, which macrofossils can clarify (Birks, 1991). In alpine regions, fluctuations of treeline are of special interest, but the pollen signal is confounded by abundant tree pollen from the forest below. Macrofossils can reconstruct the occurrence of alpine vegetation and indicate when trees became locally present. Birks (1993, 2003) showed that large percentages of tree-*Betula* pollen in the Late Glacial of western Norway and Scotland were an artifact caused by low local pollen production and overrepresentation of long-distance pollen. Macrofossils indicated that tree-*Betula* was not present and that the pollen originated from trees growing further south in Europe or from dwarf birch (*Betula nana*). Likewise, the high percentages of tree pollen found in samples from Svalbard must derive from long-distance transport. Birks (1991) used macrofossils to reconstruct the tundra vegetation and to relate the changes in vegetation density and composition to climate change, which had been impossible to deduce from pollen analyses. Pollen influx data may indicate the local presence of trees, but near treeline pollen production may be reduced in the marginal environment. Eide et al. (2006) compared Holocene tree pollen percentages, pollen influx, and macrofossil concentrations along an altitudinal transect up a south Norwegian valley. Pollen influx values of trees present near treeline were much lower than in their main area of distribution, and an estimate of tree presence and abundance could only be obtained from the macrofossil record (Figure 15). Macrofossils and megafossils have been used to document movements in arctic treelines and tree colonization and response to late-glacial climate changes, particularly in Switzerland. The Holocene macrofossil record at Sägistalsee, Switzerland, was used to test hypotheses about the relative impacts of catchment vegetation and climate changes on the paleolimnology of the alpine lake (Lotter and Birks, 2003).

In grassland biomes, Poaceae, *Artemisia*, and Cyperaceae pollen predominate. Lower taxonomic resolution is not feasible. However, macrofossil records can be used to reconstruct Holocene prairie communities in detail and to track the movements of the prairie forest ecotone through time. In arid lands, macrofossil deposits are sparse, but accumulations of plant material in middens by rodents such as packrats are a rich source of paleovegetation information. Phytogeographical changes between the full glacial and the Holocene, and changes in distribution of vegetation types such as juniper communities in response to change in Holocene humidity have been documented. Pollen records from full-glacial Beringia have been interpreted as an extinct grassland biome, 'Mammoth Steppe.' Plant macrofossil analyses from small pond sediments, from vegetation buried by tephra, and from stomach contents or dung of animals preserved in permafrost revealed a mosaic of tundra communities differentiated largely by moisture availability. Thus 'Mammoth Steppe' could be characterized. Its components were found to have analogs with modern vegetation (Guthrie, 2001).

Figure 15 Comparison of four Holocene lake-sediment sequences along an altitudinal transect from 40 m above sea level (a.s.l.) to 1144 m a.s.l. in Setesdal valley, south Norway. Pollen percentages (filled curves), pollen influx (open curves), and plant macrofossil concentrations (histograms) of *Betula* and *Pinus* are plotted against calibrated years BP, using the same x-axis scales for each proxy for all the lakes. Data from Eide W, Birks HH, Bigelow NH, Peglar SM, and Birks HJB (2006) Holocene forest development along the Setesdal valley, southern Norway, reconstructed from macrofossil and pollen evidence. *Vegetation History and Archaeobotany* 15: 65–85, Figure 6, with kind permission of Springer Science and Business Media.

Mire vegetation often contains quantities of bryophytes that are diagnostic habitat indicators. These are infrequently represented by spores, except *Sphagnum*, but mosses are frequently recognizable in the peat and lake sediments. Together with identifications of vegetative plant remains, details of the mire communities can be reconstructed and changes in moisture availability inferred. Aquatic plants are often poorly represented by pollen, either because of low pollen production (e.g., *Potamogeton* spp.) or poorly preserved pollen often adapted for water pollination (e.g., *Najas*, *Ruppia*, *Callitriche*, *Ceratophyllum*, *Zannichellia*, *Elatine*, *Juncus*). Characeae algae can be important constituents of aquatic vegetation, but they do not produce microspores. All these taxa produce readily identifiable, often abundant, macrofossils which allow hydroseres to be tracked through time (e.g., Birks, 2000; Birks et al., 2001). In addition, many marsh taxa within Cyperaceae and Poaceae can be identified by their macrofossils. The importance of macrophytes in aquatic ecosystems is now being recognized, and there are increasing numbers of multiproxy paleolimnological studies involving macrofossil analyses.

Other Applications of Macrofossil Analysis

Macrofossils are necessary for AMS dating of terrestrial plant material. Securely identified macrofossils can be selected at fine temporal resolution. The resulting radiocarbon (^{14}C) chronology can be converted to calendar years, or it can be wiggle-matched against calibrated annual data such as tree-ring chronologies or annually laminated lake sediments thus avoiding radiocarbon plateaux (Björck and Wohlfarth, 2001). Gulliksen et al. (1998) wiggle-matched a high-resolution series of AMS dates on macrofossils and gyttja at Kråkenes, western Norway, and determined the age of the Younger Dryas–Holocene boundary at 11530 ± 40 –60 calendar years before present (BP). By using terrestrial plant material, errors produced by old carbon reservoirs in lake sediments and by noncontemporaneous material such as deep-growing roots in peat can be avoided. When terrestrial and marine fossils are dated from the same marine sediment core, the marine reservoir age and its changes through late-glacial time can be estimated (Bondevik et al., 2006). Terrestrial macrofossils can also provide precise

Figure 16 *Salix herbacea*, female plant in Norway. Photograph by H.J.B. Birks.

^{14}C ages of tephra layers, which, once dated, provide time markers in terrestrial and marine sequences (Birks et al., 1996).

The density of stomata on leaves of some species today is sensitive to atmospheric CO_2 concentration. This can be calibrated and then used to reconstruct past levels and changes in CO_2 concentration by measuring stomatal frequency on fossil leaves of the same species. This technique has highlighted shortcomings in the detail of CO_2 records measured in ice cores.

The Remarkable Versatility of *Salix herbacea*

Salix herbacea leaves are small and leathery and are frequently preserved in cold-climate deposits (Figure 16). *S. herbacea* grows in open treeless vegetation with late snow-lie, in an arctic or alpine climate with plentiful snow. Its leaves are often frequent in full- and late-glacial sediments and can form part of the early succession after the Holocene warming (e.g., Gulliksen et al., 1998). At high altitudes, they can provide a continuous Holocene record. They are often sufficiently abundant to provide material for AMS dating (e.g., Gulliksen et al., 1998). Finally, they are used for reconstructing atmospheric CO_2 changes.

How Will Plant Macrofossil Analysis Develop in the Future?

Macrofossil analysis requires good botanical knowledge of plant morphology, identification, taxonomy, and ecology, and people with these skills are rare and decreasing in numbers (Birks and Birks, 2000). However, the use of plant macrofossil analysis continues to develop. Together with artifacts made of plant material, macrofossils are the basis for paleoethnobotany and archaeobotany, and they will continue in this important role. In the future, more sophisticated studies of vegetative plant material will extend our knowledge, for example from peat and fen deposits and also from preserved animal (and human) bodies. Knowledge of the representation of vegetation and species by macrofossils is slowly increasing, in both aquatic and terrestrial (packrat) locations. More modern representation studies are needed from all types of ecosystems, to aid in the interpretation of past macrofossil records.

Plant macrofossils are being increasingly used in multiproxy studies, usually in conjunction with pollen analysis. One exciting new development is their use in hypothesis testing as at Sägistalsee (Lotter and Birks, 2003). Another new development is the testing of climate-dependent models of vegetation (forest) development through the Holocene driven by independently reconstructed temperature, against the actual forest development reconstructed by macrofossils. Discrepancies helped to differentiate between different agencies of vegetation change, namely climate and human impact (Heiri et al., 2006). Plant macrofossils will probably play a pivotal role in these newly developing modeling approaches. In a multiproxy study, they provide an essential record of vegetation development either in a mire or bog, or in a lake ecosystem (lake plus its catchment).

The role of plant macrofossils in radiocarbon chronology will continue to be essential in Quaternary geology and paleoecology. High-resolution AMS ^{14}C dates around terrestrial tephra horizons will establish these as time markers wherever the tephrae are found, especially in marine cores. Dating of terrestrial and marine macrofossils from the same sediment cores will help to establish the magnitude of the marine reservoir age and how it has varied. This will be enormously useful in correcting the marine ^{14}C chronology especially during the late-glacial climatic transition. The reconstructions of atmospheric CO_2 concentrations from stomatal density on fossil leaf cuticles need to be continued, to establish detailed CO_2 changes during the Late Glacial that are not discerned by ice-core CO_2 records, and also to reconstruct CO_2 levels in previous Quaternary and older geological periods. There have been various attempts to retrieve DNA from fossil plant material, and as DNA extraction techniques improve, fossil DNA assemblages may give information about past vegetation or the diet of extinct animals which is not already apparent from the macrofossils themselves.

Macrofossils from arid and treeless areas, where lake or peat deposits are rare, are perhaps the only means of obtaining a phytogeographic and vegetation history. Plant remains are preserved in rodent middens, alluvial deposits, and also in archaeological contexts in such areas. Macrofossils are also the best means of studying arctic and alpine phytogeography and vegetational development, as the pollen record is fraught with difficulties. Knowledge about these areas of the world, both about the natural vegetation development and also the impact of human activities on it, is steadily increasing through the application of macrofossil analysis. Macrofossil analyses, usually in the context of multidisciplinary studies, are important in evaluating human impact on lake ecosystems, revealing the history of acidification, eutrophication, and pollution and their effects on macrophyte communities and hence on whole aquatic ecosystems. The astonishing rapidity of aquatic ecosystem responses to human impact, especially in arid lands, was demonstrated through macrofossil analyses, and it is hoped that this signal has been received by organizations concerned with the management of hydrological systems and water sustainability.

Introduction

The global carbon cycle is closely linked to the Earth's climate system by a large number of processes acting over a wide range of temporal scales. Changes in the operation of the carbon cycle can be expected to result in variations in the atmospheric concentration of carbon dioxide (CO₂) and, because CO₂ is a major greenhouse gas, such variations are likely to influence global temperatures. At the same time, atmospheric CO₂ levels are to a large extent determined by climatic conditions, which makes it difficult to separate cause and effect within the coupled carbon cycle–climate system.

Documenting interactions over short (submillennial) timescales is important to improve our understanding of the role of atmospheric CO₂ in Quaternary climate change. This requires CO₂ records at very high resolution, but detection of such rapid variations in ice cores is limited by inherent smoothing resulting from molecular diffusion during air enclosure. The degree to which original CO₂ amplitudes are attenuated is mainly controlled by temperature and accumulation rate at the drilling site, and conditions in Antarctica are generally unfavorable for detection of CO₂ fluctuations lasting less than one or two centuries. Unfortunately, ice-core CO₂ records from the higher-accumulation Greenland sites are not considered reliable because of artifacts related to elevated impurity (mostly carbonate) levels in the ice.

An alternative approach, with the potential to provide CO₂ reconstructions at the necessary resolution, is based on stomatal frequency analysis of leaves of terrestrial plants preserved in Quaternary lake sediments and peat. In recent years, this

method has provided a number of CO₂ reconstructions with trends similar to those shown by ice-core records but with clear evidence for centennial-scale variability and larger amplitude of change. Many of the detected CO₂ fluctuations are temporally related to climate events of global significance, which points to the importance of carbon cycle–climate interaction also on submillennial timescales during the Quaternary.

Basis of the Method

The outer surface of vascular plants is covered by an impermeable layer called the cuticle, and gas exchange with the atmosphere is primarily restricted to small pores – stomata – that are primarily located on leaves ([Figure 1](#)). Through the control of stomatal aperture and number of stomata that develop on the leaf surface, this arrangement allows the plant to maximize CO₂ supply for photosynthesis and minimize water loss from transpiration, that is, to optimize water use efficiency. Stomata form early in leaf development ([Tichá, 1982](#)), and their initiation is largely determined by ambient CO₂ conditions. The relationship between atmospheric CO₂ concentration and stomatal frequency is an inverse one; more leaf surface (epidermal) cells develop into stomata at low concentrations and vice versa. Although the mechanism governing stomatal initiation is not fully understood, stomatal frequency represents an important physiological plant response that is detectable in the fossil record.

Adaptation of naturally growing plants to changing CO₂ levels was first noticed by [Woodward \(1987\)](#) for herbarium

Figure 1 (a) Leaf of *Salix herbacea*. The five black squares distributed over the leaf surface indicate suitable field areas for counting of stomata and epidermal cells. (b) Field area of a *S. herbacea* leaf seen through an epifluorescence microscope. The upper left corner of the picture where no stomata are seen covers part of a major vein. The black square indicates an interveinal area suitable for counting. (c) Close-up of the black square in (b). Four entire stomata, and another three that cross the border of the field area, are seen together with epidermal cells.

leaves of temperate tree species collected since the mid-eighteenth century, and a CO₂ response has later been shown for more than a hundred species, both in herbarium studies and controlled experiments (Royer, 2001). Basically, each new leaf that develops on a plant becomes adjusted to the ambient conditions, which means that stomatal frequency analysis of fossil leaves has the potential to reconstruct annual CO₂ changes. In practice, however, very few Quaternary leaf sequences have the necessary resolution to allow CO₂ reconstruction on subdecadal timescales.

Stomatal frequency data may be quantified in two different ways. Stomatal density (SD) is simply a measure of the number of stomata per unit leaf area (expressed in mm⁻²). Stomatal index (SI) quantifies the proportion of the total number of leaf surface cells (stomata and epidermal cells) that are stomata, where a stoma consists of the stomatal pore and two flanking guard cells (Figure 1). The SI, which is expressed as a percentage, was introduced by Salisbury (1927) and is often defined as $SI = SD / (SD + ED) \times 100$, where ED is epidermal cell density (mm⁻²). Because SI is a proportional measure, it is unaffected by leaf expansion and therefore the preferred parameter for CO₂ reconstruction. In comparison, SD is influenced both by stomatal initiation and leaf expansion, which makes it sensitive to environmental factors other than CO₂, particularly light, temperature, and water conditions. Many experiments and field studies have shown a SD response to these parameters, while there are few indications of an influence on SI (Beerling, 1999; Royer, 2001; Wagner et al., 2004). Consequently, CO₂ reconstructions based on SD are considered less secure.

Outline of the Method

Site Selection

The prime requisite for a site to be used in a stomatal frequency study is, of course, that it should show a high concentration of fossil leaves. Such sites are hard to find, and this is a major limiting factor. As for plant macrofossil studies in general, it is difficult to predict if a site contains an abundant leaf record, but some recommendations for the selection of suitable lake sites can be made (Birks, 2001).

Because the CO₂ response is species specific (Rundgren and Björck, 2003), it is desirable to find leaf sequences with

continuous presence of a single species over long periods of time. When two or more species are combined to extend a reconstruction, the individual leaf records should preferably overlap in some interval (Rundgren and Björck, 2003; Rundgren et al., 2005). Although it is possible to estimate CO₂ concentrations from single leaf occurrences, precision increases significantly with the number of leaves per sample. Ideally, three to five leaves of a species should be available from each level. *Betula pendula*, *Betula pubescens*, *Salix herbacea*, *Quercus robur*, and *Quercus petraea* are among the species that have most frequently been used for CO₂ reconstruction, which partly reflects their relative abundance and good preservation potential in Quaternary lake sediments and peat.

Most CO₂ reconstructions have been based on lake sediments, but leaves extracted from bog and swamp peat and leaf litter have also been used. So far, stomatal frequency studies have predominantly been conducted in temperate and Arctic environments. Low-latitude areas are, however, receiving increased attention (Wagner et al., 2005), partly because their generally more stable climatic conditions during glacial–interglacial cycles imply a potential for long and continuous leaf sequences.

Sampling

The strategy for sampling is consistent with plant macrofossil studies in general and depends on the type of site and source material (Birks, 2001). When coring in lake sediments and peat, several parallel cores may be needed to obtain sufficient leaf material. Cutting of cores, especially at intervals of <1 cm, must be done carefully to minimize destruction of leaves.

Sample Preparation

Samples are processed according to standard methods for plant macrofossil analysis (e.g., Birks, 2001). If treatment with sodium hydroxide (NaOH) is needed, precautions should be taken that there is no damage to the leaves, and tests should be performed to design a suitable treatment before applying it to all samples (Rundgren et al., 2005). A sieve with mesh size of 500 μm is sufficient to catch leaves and leaf fragments. Any fragment passing through this mesh size will be too small for stomatal frequency analysis. Leaves are generally delicate structures and require gentle treatment in the sieving process and during subsequent handling.

Identification

Whole leaves and large fragments are usually identifiable during sorting of the sieving residue using a stereomicroscope with the aid of standard floras and a reference collection. Small leaf fragments do, however, often require closer examination and may be identified later at the counting stage based on cuticular characteristics. Cuticle examination may also support identification in ordinary plant macrofossil studies. If not immediately subjected to further analysis, leaves should be stored in water in a cool place or frozen to prevent bacterial and fungal growth over a long period.

Leaf Preparation

If an epifluorescence microscope is to be used for counting, no further preparation is needed, except cleaning leaf surfaces from any remaining mud with a brush. After that, each leaf fragment to be counted may be placed together with glycerine on a microscope slide and covered by a cover slip. If a normal light source is used, cuticles need to be isolated from the fossil leaves. Areas of about 0.5 cm × 0.5 cm are cut out with a scalpel and bleached in 4% NaHClO₂ solution to remove the mesophyll. This may take from a few minutes up to many hours. The remaining cuticles are separated, stained with safranin, and mounted in glycerine jelly on microscope slides.

Counting

Counting of stomata and epidermal cells is conducted using epifluorescence or transmitted light microscopy. In the first method, fluorescent light reaches the leaf from above through the objective, and excitation highlights cell walls and other structures on its surface. In the second method, normal light from below passes through the isolated and stained cuticle and makes its morphological features visible.

The size of the field area used for counting varies among species and is optimized with regard to cuticular morphology, in particular cell size. A larger field of view results in more representative values but, in practice, field size is limited by the distribution of veins on the leaf surface (Figure 1). Field area size should be selected so that, in general, at least five stomata (including two flanking guard cells) and 50 epidermal cells are visible, and the same size should be used throughout the study. Typically, field areas of 0.03–0.06 mm² and magnifications of 200–600× are used.

Stomata and epidermal cells can be tallied directly at the microscope using, for example, a hand counter. In this case, a graticule in one of the eyepieces is normally used to define the field area and facilitate counting. Alternatively, if a camera is attached to the microscope and linked to a computer, counting may be made (immediately or at a later time) with the aid of image analysis software. Although slightly more time consuming, this arrangement enhances counting accuracy and allows images of all counted fields to be conveniently archived for later study. Irrespective of counting procedure, stomata and epidermal cells are usually counted within a rectangular or quadratic area, and standardized criteria for how to deal with stomata (including two flanking guard

cells) and epidermal cells along the field area margin are needed. An appropriate approach is that described by Poole and Kürschner (1999), where all stomata and epidermal cells crossing two predefined sides of the field area and the corner between them are included in the count, while those crossing the two remaining sides and the three remaining corners are not (Figure 1).

To minimize the effect of intraleaf variability, counts should be made from several field areas distributed over the leaf surface and used to calculate leaf SI and SD mean values. These areas should, however, not be placed along margins, or near the leaf base or tip, where stomatal frequency values often are found to be anomalous (Poole et al., 1996; Tichá, 1982; Figure 1). To minimize variability caused by the presence of veins that do not carry stomata, counting should also be restricted to interveinal areas. The specific number of counts needed to produce reliable mean values varies from species to species and should be determined in a pilot study (Poole and Kürschner, 1999). This may be done through successive calculation of the mean as more counts are added. Fluctuation of the mean is typically found to be within acceptable limits after 7–10 counts per leaf. The number of counts needed is partly dependent on stomatal arrangement, with hypostomatous species (having stomata only on the lower leaf surface) normally found to require fewer counts than amphistomatous species (having stomata on both surfaces). To account for interleaf variability, sample SI and SD mean values are calculated based on leaf (or leaf fragment) mean values and used in CO₂ calibration. It should, however, be noted that it is not always possible to determine if small-sized fragments are derived from separate leaves.

The counting procedure described above only applies to broad-leaved angiosperm species. Gymnosperms exhibit a different mode of leaf development and stomatal patterning, which requires alternative approaches. Different parameters have been used to quantify stomatal frequency in conifer needles, including SD and number of stomatal rows. In contrast to the situation in broad-leaved species, stomatal initiation is usually more accurately reflected by SD rather than SI in conifers, but the number of stomata per millimeter of needle length is considered to be the most sensitive parameter (Kouwenberg et al., 2003). The often weak CO₂ responses found in earlier studies of conifer species (Royer, 2001) may partly be due to inappropriate quantification of stomatal frequency.

Calibration

Atmospheric CO₂ concentration at the time of growth is reconstructed through calibration of stomatal frequency data based on a modern training set (Figure 2). Although stomatal responses generally are species specific, similarities in CO₂ response may allow reconstruction with training sets including closely related species (Jessen et al., 2005; Rundgren et al., 2005; Wagner et al., 1999). Calibration datasets are generally obtained from modern or herbarium leaves collected from plants growing in natural environments, or a combination of both. Also leaves from well-dated shallow peat cores are sometimes used (Kouwenberg et al., 2005; Wagner et al., 1999).

Figure 2 Examples of modern training sets used to reconstruct past CO₂ levels from fossil stomatal frequency data. The calibration data shown are based on a combination of herbarium material (dating back to 1840) and modern leaves collected along altitudinal gradients and were applied to stomatal index (SI) data obtained from *S. herbacea* and *Salix polaris* leaves preserved in Swedish late-glacial and Holocene lake sediments (Rundgren and Beerling, 1999; Rundgren and Björck, 2003). Lines through the data represent linear regressions (with 95% confidence intervals). Adapted from Rundgren M and Björck S (2003) Lateglacial and early Holocene variations in atmospheric CO₂ concentration indicated by high-resolution stomatal index data. *Earth and Planetary Science Letters* 213: 191–204, with permission.

Leaves from plants grown in controlled CO₂ environments are, however, usually discarded because of concerns that stomatal responses to the often abrupt and high-amplitude CO₂ changes applied in experiments are unrepresentative of those recorded by fossil leaves, which developed under natural conditions.

The use of modern leaves in calibration is based on the observation that plants respond to changes in CO₂ partial pressure rather than CO₂ concentration (Woodward and Bazzaz, 1988). Because CO₂ partial pressure decreases with altitude, as a consequence of lowered air pressure, leaves collected along an altitudinal gradient provide a series of calibration data points. The herbarium approach takes advantage of the marked industrial CO₂ increase documented over the last two centuries from atmospheric measurements and high-resolution ice cores. With information about the year (and altitude) of collection, the CO₂ conditions experienced by the plant represented by the herbarium specimen may be calculated.

To capture the nature of the response and minimize error estimates on reconstructed CO₂ values, modern leaves should be selected to cover a CO₂ gradient as wide as possible. This also reduces the need for extrapolation in the calibration process. Because detailed CO₂ data are only available for the last few hundred years, however, reconstruction of very low (e.g., glacial) CO₂ values will inevitably involve extrapolation. Calibration datasets applied in CO₂ reconstruction generally show r^2 (coefficient of determination) values, as determined by

linear regression, in the range 0.5–0.8. In theory, however, any stomatal frequency response to CO₂ is expected to follow a sigmoidal rather than a linear function (Kürschner et al., 1997). This is because leaves may neither lack nor attain an infinite number of stomata. Although there are indications that some species are currently approaching, or already have reached, their response limit (Kürschner et al., 1997; Wagner et al., 2004), most modern training sets are adequately described by linear models (Figure 2). Calibration datasets must, of course, be produced following the same analytical protocol used to obtain fossil data. Consequently, to enable a calibration dataset to be applied in other fossil studies, it is important to provide details about how it was produced.

Calibration of stomatal frequency data has been performed both by inverse and classical (linear) regression. In some instances, stomatal frequency and CO₂ data have been log-transformed prior to calibration in order to account for the partial nonlinear CO₂ response indicated for some species at the high CO₂ concentrations experienced in recent decades (Wagner et al., 2004, 2005). Calibration also involves calculation of confidence intervals for the obtained CO₂ estimates. Both a high r^2 value for the modern training set used, and good replication of fossil data (many leaves counted per sample), contributes to produce narrow intervals. If fossil leaves are derived from a high-altitude site where partial pressure is significantly lower than at sea level, all reconstructed CO₂ values need to be adjusted for this pressure difference before they are converted to concentrations.

Presentation of Results

CO₂ estimates should be displayed together with their calculated confidence intervals. In high-resolution studies, some degree of smoothing is often applied to raw sample values in order to account for the inherent scatter in biological systems and to illustrate more realistic rates of change. When new indicator species are introduced, the calibration data used should be presented graphically.

Overview of CO₂ Reconstructions Based on Stomatal Frequency

Fossil Responses

Following the demonstration, based on herbarium material, that plants have adjusted their stomatal frequency in response to increasing CO₂ concentrations over the last two centuries (Woodward, 1987), a number of fossil studies have also provided evidence for responses on Quaternary timescales (Beerling, 1993; Beerling et al., 1992, 1993; McElwain et al., 1995). These early studies on Saalian, Weichselian, late-glacial, and Holocene leaves were, however, based on isolated samples. Stratigraphic data supporting a CO₂ response was later presented by Wagner et al. (1996), who demonstrated marked SD and SI reductions for an individual *B. pendula* tree growing on a Dutch peat bog in the period 1952–95. Although not stratigraphically constrained, the well-dated SD data obtained from *Pinus flexilis* needles preserved in packrat middens in Western United States (van de Water et al., 1994) clearly illustrate

a stomatal frequency response to CO₂ changes on glacial-interglacial timescales.

Late-Glacial and Holocene Reconstructions

The first attempt to actually reconstruct Quaternary CO₂ levels was made by Beerling et al. (1995) based on late-glacial and early Holocene lake sediments from western Norway with a high concentration of *S. herbacea* leaves. Their study, which was based on SD data, reconstructed CO₂ concentrations around 275 parts per million by volume (ppmv) during the late Allerød (late AL equivalent to the end of Greenland Interstadial 1 (GI-1) (Björck et al., 1998)), followed by a rapid decrease to ~210 ppmv at the beginning of the Younger Dryas (YD, equivalent to Greenland stadial 1 (GS-1)). CO₂ concentrations increased gradually through the YD to reach about 270 ppmv at the opening of the Holocene and then continued to rise for another ~300 years. Another CO₂ reconstruction covering a similar interval (12 800–10 800 cal years BP) was presented by Rundgren and Björck (2003), who combined partly overlapping high-resolution sequences of *Salix polaris*, *S. herbacea*, and *Betula nana* leaves from the sediments of a lake in southwestern Sweden (Figure 3). This SI-based record

exhibits the same pattern of late-glacial CO₂ change, and similar absolute values, as found by Beerling et al. (1995). In addition, the Swedish study clearly indicates a short-lived reduction in CO₂ concentrations a few centuries into the Holocene that was suggested to be related to the Preboreal oscillation (an early Holocene cooling event; Björck et al., 1997). A third late-glacial-to-early Holocene CO₂ reconstruction based on SD data has been obtained from *Dryas integrifolia* leaves and *Picea mariana*, *Picea glauca*, and *Larix laricina* needles extracted from two ponds in Atlantic Canada (McElwain et al., 2002). In accordance with the other studies, this record shows a clear CO₂ decrease at the AL/YD (GI-1/GS-1) transition. It differs, however, by indicating consistently low YD concentrations (~235 ppmv), followed by a CO₂ rise at the transition to the Holocene, back to levels similar to those at the end of the Allerød (~300 ppmv). A temporary CO₂ decrease, possibly related to the one detected by Rundgren and Björck (2003), is seen in the record with the highest early Holocene resolution.

The first evidence of a century scale, early Holocene (Preboreal) CO₂ oscillation was, however, presented by Wagner et al. (1999), who analyzed the SI of *B. pendula* and *B. pubescens* leaves in lake sediments and peat deposited in an abandoned river channel in the Netherlands. According to results from a

Figure 3 Stomatal-based CO₂ reconstruction through the late-glacial and early Holocene (Rundgren and Björck, 2003). The reconstruction is based on SI data for partly overlapping leaf sequences of three species (*S. herbacea*, *S. polaris*, and *Betula nana*) preserved in the sediments of a Swedish lake, and the curve shown represents the smoothed combined CO₂ record (5-point running mean values). Also shown is the CO₂ record from the Antarctic Dome C ice core (Monnin et al., 2001). The oxygen isotope record from the Greenland Ice Project (GRIP) ice core (Johnsen et al., 2001) illustrates the general temperature development in the North Atlantic region. AL, Allerød interstadial; YD, Younger Dryas stadial. GI-1 and GS-1 are the equivalents to AL and YD in the INTIMATE event stratigraphy (Björck et al., 1998). Age of Preboreal oscillation according to Björck et al. (1997). Adapted from Rundgren M and Björck S (2003) Lateglacial and early Holocene variations in atmospheric CO₂ concentration indicated by high-resolution stomatal index data. *Earth and Planetary Science Letters* 213: 191–204, with permission.

later attempt to date the sequence in detail (van der Plicht et al., 2004), their data indicate a temporary CO₂ decrease (from a general Preboreal level around 340 ppmv) between ca. 11 250 and 11 100 cal years BP. In addition, CO₂ increased distinctly following the YD/Holocene transition. A compilation of all stomatal evidence for a Preboreal CO₂ fluctuation was presented by Wagner et al. (2004). Following its publication, yet another record showing a clear early Preboreal CO₂ decrease has been produced from a temporally detailed SI study of *S. herbacea* leaves preserved in the sediments of a lake in the Faroe Islands (Jessen et al., 2007). As shown in this study, the short-lived Preboreal CO₂ fluctuations indicated by the Dutch, Swedish, and Faroese records all overlap in age when errors in radiocarbon dates are taken into account (Figure 4), which suggests that they all reflect the same event. In the Faroese record, which covers the period ca. 11 200–10 300 cal years BP, the early Preboreal event is followed by a series of CO₂ oscillations within the range 320–340 ppmv. When compared with records spanning the late-glacial-to-early Holocene transition (Beerling et al., 1995; McElwain et al., 2002; Rundgren and Björck, 2003), the two Preboreal

Figure 4 Comparison of three early Holocene stomatal-based CO₂ reconstructions from sites in the Netherlands (Wagner et al., 1999, 3-point running mean values), Sweden (Rundgren and Björck, 2003, 5-point running mean values), and the Faroe Islands (Jessen et al., 2007, 5-point running mean values). The figure illustrates that a century-scale CO₂ decrease centered at ca. 11 100 cal years BP (according to the Faroese age model) and believed to be related to the Preboreal oscillation (Björck et al., 1997) is reproduced by three independent stomatal frequency studies. Also shown is the CO₂ record from the Antarctic Dome C ice core (Monnin et al., 2001), which does not show any evidence of the CO₂ decrease reconstructed by stomatal frequency analysis.

reconstructions detailed above show overall unexpectedly high CO₂ concentrations. Potential explanations for such divergent and consistently elevated CO₂ estimates – also relative to ice-core records – are discussed toward the end of this review.

Rundgren and Beerling (1999) presented a CO₂ record for the past 9000 years based on SI data obtained from a remarkably long sequence of *S. herbacea* leaves preserved in the sediments of a lake in northern Sweden. Although the leaf record is sparse prior to ca. 5000 cal years BP, the reconstruction clearly indicates an overall CO₂ increase from levels of ~270 ppmv at this time up to the present day. The high-resolution data available for the remaining part of the Holocene shows, however, that this millennial-scale trend was punctuated by a marked period of lower CO₂ levels between ca. 1000 and 500 cal years BP (AD 950–1450), and the industrial CO₂ rise is clearly visible in the record. The period 8700–6800 cal years BP was studied in more detail by Wagner et al. (2002), who analyzed *B. pendula* and *B. pubescens* leaves from a Danish lake sediment sequence. They found evidence for a ~25 ppmv CO₂ drop (from a level of ~300 ppmv) between ca. 8400 and 8000 cal years BP that was suggested to be related to the so-called ‘8.2 ka BP event,’ a cooling event of possibly global significance (Rohling and Pälike, 2005). A short-lived CO₂ decrease at this time may also be present in the Holocene record from northern Sweden (Rundgren and Beerling, 1999; Wagner et al., 2004).

The CO₂ evolution of the last ~1200 years was studied in detail by Kouwenberg et al. (2005) based on stomatal frequency (number of stomata per millimeter of needle length) analysis of *Tsuga heterophylla* needles preserved in the sediments of a pond in Northwestern United States. They reconstructed a series of centennial-scale CO₂ fluctuations around a preindustrial average of 280–290 ppmv, with the most pronounced minima centered on ca. AD 850 and 1150, and with maxima at ca. AD 1000, 1300, and 1700. The pattern of change was compared with paleoclimatic records from various regions, and it was concluded that a coupling has existed between atmospheric CO₂ and climate during the last millennium. Another CO₂ record covering part of the same period (c. AD 1000–1500) has been produced using SI data from *Q. robur* leaves derived from a Dutch river channel deposit. This record is consistent with that of Kouwenberg et al. (2005) in showing a distinct CO₂ increase between ca. AD 1200 and AD 1300, but absolute values are generally higher (~290–320 ppmv).

Eemian Reconstructions

S. herbacea leaves extracted from sediment samples collected in East Greenland and known to be of last interglacial age were analyzed for SI by Rundgren and Bennike (2002). A majority of these samples, for which there was no stratigraphic control, yielded typical interglacial CO₂ values (250–280 ppmv), but two lower estimates were taken to indicate century-scale variability during the Eemian. CO₂ levels during the last interglacial were investigated in more detail by Rundgren et al. (2005), who analyzed SI of *B. pendula*, *Q. robur*, and *Q. petraea* leaves from a Danish lake deposit. They reconstructed concentrations between 250 and 290 ppmv, and a marked centennial to millennial variability, during the first 3000 years of the Eemian. CO₂ levels were more stable, and slightly higher (290–300 ppmv), during the following three millennia. Based on

pollen stratigraphic correlations, the observed shift in CO₂ dynamics was coincident with a major climatic transition (the end of the Eemian climatic optimum) in northwestern Europe.

Potential and Limitations of the Method

It is clear from the overview presented above that stomatal frequency analysis has become increasingly and successfully applied in Quaternary science over the past two decades. These studies, which have been based on leaf sequences derived from a range of species and sampled from sites with a wide geographic distribution, have contributed important information about CO₂ dynamics during various parts of the Quaternary. In particular, they have provided ample evidence for century-scale CO₂ variability, which is rarely detected in more traditional ice-core studies. In a Quaternary perspective, this ability to detect short-term variations is probably the largest merit of the method because it enables high-resolution CO₂ and climate records to be compared in order to better understand carbon cycle–climate interactions on submillennial timescales. The potential of this type of exercise is particularly large when stomatal frequency and climate proxy data are available from the same sediment or peat sequence (Jessen et al., 2005; Rundgren et al., 2005). In addition, stomatal frequency analysis has the potential to provide high-resolution CO₂ reconstructions for Quaternary (and earlier) intervals that are beyond the reach of ice cores (e.g., McElwain et al., 2005; Royer et al., 2001).

It should, however, be acknowledged that the stomatal frequency method is still in a stage of development. A fundamental test of the reliability of any method is, of course, its performance in relation to other methods. Quaternary CO₂ records are traditionally based on analysis of air bubbles enclosed in polar ice cores (Stauffer), and this is presently the most widely accepted method. On a multimillennial timescale during the Holocene, stomatal-based CO₂ reconstructions show trends very similar to ice cores (Rundgren and Beerling, 1999). For the late Holocene, a good agreement in trends is also found on centennial timescales (Kouwenberg et al., 2005; Rundgren and Beerling, 1999; van Hoof et al., 2005). The century-scale CO₂ fluctuations seen in early Holocene stomatal-based reconstructions (Jessen et al., 2007) (Rundgren and Björck, 2003; Wagner et al., 1999, 2002) are, however, not evident in ice-core records (Figures 3 and 4). The situation is similar during the YD (GS-1), where stomatal frequency reconstructions show a CO₂ decrease, at the same time as ice-core records are characterized by a slow and steady rise in CO₂. Overall, the late-glacial trend is similar for stomatal and ice-core-based data (McElwain et al., 2002; Rundgren and Björck, 2003; Figure 3), but the stomatal reconstructions show a temporally more detailed record connected to the climate changes around the YD.

In summary, stomatal frequency analysis has the capacity to reconstruct millennial-scale CO₂ trends consistent with ice-core records. Moreover, centennial-scale trends are similar for the two methods during the late Holocene. This suggests that stomatal frequency analysis is an adequate method for CO₂ reconstruction and that there is only limited influence from

other environmental factors on the results, at least for SI-based reconstructions. For the early Holocene and older periods, however, century-scale CO₂ variability is not apparent in ice-core records but is seen in stomatal-based reconstructions. This discrepancy does not necessarily reflect flaws in the stomatal frequency method; it may as well be an indication that the effect of diffusional smoothing on CO₂ records from deep ice cores is currently underestimated. As shown by Wagner et al. (2004), both late and early Holocene century-scale CO₂ fluctuations are reproduced in a number of stomatal frequency reconstructions from different species and geographic regions, which strengthens the credibility of the method.

The consistently larger CO₂ amplitude in stomatal-based reconstructions, compared to ice-core records, may partly be explained by a combination of the generally larger scatter in biological proxy data and diffusional smoothing of CO₂ concentrations measured in ice cores. The contribution of the latter process was investigated by van Hoof et al. (2005) by applying a firn diffusion model, constrained by site-specific parameters for a high-resolution Antarctic ice core, to a stomatal reconstruction between AD 1000 and AD 1500. This resulted in a 25% reduction of the amplitude and a CO₂ record consistent with the ice core.

When the CO₂ reconstructions reviewed above are compared with ice-core records, it is clear that many stomatal frequency studies provide Holocene CO₂ estimates consistently slightly higher than shown by ice cores. This discrepancy is difficult to explain. Higher CO₂ concentrations at the time of bud-burst at high-latitude sites relative to the mean annual levels reflected by ice cores can only account for a minor part. Possibly, the answer lies in partly inadequate calibration datasets, and efforts are now being made to improve CO₂ inference models (Wagner et al., 2005). Difficulties in obtaining stomatal frequency data representative of very low CO₂ concentrations are, however, likely to continue to obstruct quantification of CO₂ levels during glacial periods.

Introduction

The northern treeline zone has long been the focus of study by Quaternary paleoclimatologists and paleoecologists. The geographic position of the circum-Arctic treeline is controlled by global climate patterns. As trees growing in the treeline zone are at their physiological range limits and sensitive to environmental perturbations, studies of past treeline shifts can provide information on the form and rate of response of trees and forest plant communities to climatic changes, and reconstructions of past treeline movement provide insights into past variations in climate. In addition, special attention has focused upon the northern treeline because large geographic shifts in this zone can produce feedbacks that amplify the impacts of climate change (Foley et al., 1994). Quaternary scientists have used several lines of evidence to study past climate and vegetation at treeline, including fossil pollen and fossil stomata from lake sediments and peats, macrofossils such as preserved conifer needles, and paleopedological records. One of the most striking and direct forms of evidence pertaining to past northward advances of the northern treeline comes from wood megafossils that have been recovered and analyzed from a number of locales in North America and Eurasia.

Current Treeline Location, Vegetation, and Climatic Controls

The northern treeline is best thought of as a zone of transition across which continuous forest cover of the boreal forest gives way to increasingly scattered fragments of forest and smaller and smaller individual trees (Figure 1). Eventually, the ultimate species' limits for trees are reached and the vegetation becomes a treeless tundra. The extent of this transitional zone can range from a few kilometers to over a hundred kilometers. At the extreme northern limits of their distributions, coniferous species often grow in a low, contorted and ground-hugging form called *krummholz* (twisted wood; Figure 2). The current position of the northern treeline zone (Figure 3) lies generally between 60° and 70° N latitude. The circumpolar treeline descends southward to below 60° N in central Canada and ascends northward to 73° N in the Taimyr Peninsula region of central Siberia. In Europe, the dominant treeline conifers include *Pinus sylvestris* L. (scots pine), *Picea abies* (L.) Karst. and *Picea obovata* Ledeb. (Norway and Russian spruce), and *Larix sibirica* Ledeb. (Siberian larch). In northern Asia, the dominant treeline conifers include larches (*L. sibirica* and *Larix dahurica* Turcz. ex Trautv.) and *Pinus pumila* (Pall.), Regel (stone pine) in the far east. *Pinus sylvestris* and *Picea* are found in the boreal forest of northern Asia, but are not generally present as far north as the treeline in that region. In North America, the dominant coniferous trees include *Picea glauca* (Moench), Voss (white spruce), *Picea mariana* (P. Mill.) BSP (black

spruce), and larch (*Larix laricina* (Du Roi) K. Koch). *Pinus banksiana* Lamb. (jack pine) is found in the northern boreal forest, but does not grow at treeline. Broadleaf trees such as birch (*Betula*) and poplar (*Populus*) can also be found in the North American and Eurasian treeline zones. In northern Scandinavia, the treeline is formed by *Betula pubescens* ssp. *czerepanovii* (Orlova) Hamet-Ahti.

Cool summer temperatures coupled with a short growing season appear to be the ultimate reason why trees do not grow further north in the Arctic. Air and soil temperatures are too cool and the growing season is too short for trees to conduct adequate photosynthesis to meet growth and reproductive requirements. Sexual reproduction is usually rare for *krummholz* trees and propagation is often by vegetative layering. Very cold winter temperatures can limit tree occurrence for some species such as *Pinus sylvestris*, and damage to buds and needles by blowing snow in the winters can also limit growth or establishment of trees. The treeline zone typically occurs (Figure 3) where the average July temperatures lie between 12.5 and 10.0 °C (MacDonald, 2002). The treeline also roughly corresponds to the average July position of the Arctic Frontal Zone. Areas north of this frontal boundary are dominated by cold and dry polar air masses. Thus, the geographic position of the treeline is related to both general latitudinal patterns of decreasing insolation and general atmospheric circulation. Average winter temperatures have a much greater range than summer temperatures when treeline sites in North America and Eurasia are compared. Average January temperatures range from only –10 to –15 °C at the Fennoscandian treeline in northwestern Europe, between –20 and –25 °C for much of the North American treeline and below –40 °C for some regions of central Siberia.

The location of treeline is ultimately controlled by climate, but the presence or absence of trees also affects the climate. The dark foliage and rough canopy of forested areas absorb more sunlight than light colored and smooth tundra surfaces, and this is important for planetary albedo and radiation fluxes. Climatological models suggest that if the treeline were to significantly advance northward, this could actually produce a significant increase in the temperature for the entire earth surface due to the increased capture of solar energy by the dark forest cover. Model experiments suggest that pronounced northward extensions of treeline in the Quaternary might have played a role in global patterns of climate warming (Foley et al., 1994).

The general correspondence between summer temperatures and the geographic position of the modern treeline leads to the conclusion that past shifts in treeline likely reflect changes in summer thermal conditions in the Arctic and sub-Arctic. In simplest terms the presence of trees might be used to infer minimum average July temperatures of 12.5–10.0 °C at that location. The use of treeline to infer winter conditions is more problematic. Due to the relationship between

Figure 1 An aerial view of the *Picea* dominated northern treeline zone of central Canada showing the transition from denser forest cover in the south to scattered small trees and krummholz at treeline (© Glen M. MacDonald).

Figure 2 Krummholz *Larix dahurica* near the Lena River delta in eastern Siberia with a pocket knife for scale (© Glen M. MacDonald).

summer temperatures and the Arctic Frontal Zone, reconstructions of treeline position can cast light upon both insolation-driven thermal changes and those attributable to changes in atmospheric circulation patterns (MacDonald et al., 1993, 2000b; Ritchie and Hare, 1971; Ritchie et al., 1983).

Wood Megafossil Analysis and the Interpretation of Past Treeline Shifts

The occurrence of ancient tree stumps on the presently treeless tundra has been known since at least the reports of A.F. Middendorf from Siberia in the 1860s. Megafossils of wood, which includes trunks, branches, and roots of conifer and broadleaf trees, have now been recovered from a number of areas beyond the modern treeline in North America and Eurasia. In some cases, these megafossils are found in rooted growth position or lying near their former point of growth on the tundra surface (Figure 4(a)). Such wood might be preserved for thousands of years in the Arctic tundra for several reasons:

1. The cold temperatures and brevity of the warm season in the Arctic and northern sub-Arctic restrict microbiological and macrobiological decomposition rates.
2. The relatively dry conditions of many Arctic and sub-Arctic sites further restrict decomposition rates.
3. The radial growth rates for northern trees are often very slow, producing narrow growth rings and very dense wood, which is more resistant to water infiltration and rot than fast growing, less dense wood.
4. Fire frequency in sparsely wooded treeline and tundra sites is generally extremely low, limiting the chance that wood will be consumed by fire.

Figure 3 The relationship between the location of the northern treeline and mean July temperature.

Figure 4 Early to mid-Holocene wood megafossils: (a) *Larix* log lying on the tundra surface on the Taimyr Peninsula, Russia, (b) *Pinus* stump in the shallow waters of a small lake on the Kola Peninsula, Russia, and (c) *Larix* stumps covered with colluvium and subsequently exposed by stream erosion near the mouth of the Lena River, Russia (© Glen M. MacDonald).

5. Human population densities are generally low in the tundra zone, limiting, although not completely restricting, the removal or use of wood by people.

In addition to being found on the surface, wood megafossils are commonly preserved in the waters and sediments of lakes, peatbogs, fluvial deposits, and colluvium (Figure 4(b) and 4(c)).

Field sampling strategy to collect megafossils varies. In some cases, systematic foot surveys and transects are done of the tundra surface or along stream channels and other exposures. The waters of lakes can also be surveyed to find material

lying on top of the sediment. Megafossils can be recovered from some lake or peat cores. Finally, newly exposed landscapes created by the recent melting of perennial snowbanks or glacier fronts can reveal megafossils from previous warm periods. The use of geographic positioning systems (GPS) to provide exact coordinates of the finds, careful note taking, and photographic documentation of the finds are important components of the field work.

Identification of wood megafossils can typically be done to the level of genus using thin sections of wood to examine the characteristics of the xylem cells and associated structures

(Core et al., 1979; Hoadley, 1990). The absence of vessels identifies the wood as a gymnosperm (Pinophyta). An example of a simple key for some typical boreal gymnosperm genera is as follows:

1. Resin ducts normally present.
 - (a) Wood with abrupt latewood–earlywood transition.
 - (b) Ray tracheids present – *Larix*.
 - (c) Wood with gradual transition.
 - (d) Cross-field pits large with indistinct borders – *Pinus*.
 - (e) Cross-field pits small and bordered – *Picea*.
2. Resin ducts normally absent.
 - (a) Ray tracheids absent and walls of ray cells conspicuously pitted – *Abies*.

Two approaches are generally used to provide chronological control for the wood megafossils. First, samples which are more than 200 years and less than 40 000 years in age can be radiocarbon dated. Typically, the precision of such estimates ranges from 100 to 500 years. If at all possible, a portion of any sample submitted for radiocarbon dating should be archived to serve as a voucher specimen should further analysis or verification be required. Dendrochronological cross-dating has been used to assign ages to wood megafossil samples dating from the past 300 to 1000 years in many studies of treeline dynamics in the Western and Eastern hemispheres. In certain areas, such as northern Fennoscandia and the Polar Urals–Yamal Peninsula region, dendrochronological techniques have begun to be used to produce tree-ring chronologies that can be used to cross-date megafossils back millennia (e.g., Shiyatov et al., 1996; Zetterberg et al., 1996), and such efforts will likely bear fruit elsewhere in the treeline zone. Such cross-dated samples provide exact calendar year dating control for the samples.

When care is taken in the collection, identification, and dating of the megafossil, it can be used as evidence for the past minimum northern position of the treeline. Megafossils can be collected from currently treed sites at treeline to provide a minimum age for the establishment of tree populations at the site. When large collections are made of many samples, the changes in the number of samples recovered from different time periods can potentially provide evidence of changes in forest density in the past (MacDonald et al., 2000b).

Fossil pollen studies of lake sediments and peat sections have long been used to reconstruct treeline history for the Holocene. However, this approach suffers from the often poor spatial resolution of pollen records, which are generally dominated by wind dispersed taxa that can be carried tens to hundreds of kilometers from parent trees. This is exacerbated by the low pollen productivity of tundra vegetation, which allows the pollen signal from tundra sites to be dominated by long-distance dispersed tree pollen from the south. For example, in Canada it is not unusual to record *Picea* pollen percentages of over 10% from lakes located in the tundra over 100 km or more, north of any living spruce trees (Gajewski, 2002). So long as sampling is conducted away from beaches or north flowing rivers where long-distance transported wood might occur, the use of wood megafossils can provide a more spatially explicit means of recording past treeline location because the tree likely grew at the site the megafossil is recovered.

Although wood megafossils are not prone to the long-distance transport problems that affect pollen-based estimates

of past treeline, because of their inherent scarcity in many regions, wood megafossils might sometimes provide only minimum age estimates of the timing of tree species' arrival in a region or of actual range limits. A comparison of the fossil pollen record, the fossil conifer stomata record, and the wood megafossil record from a small lake lying beyond the modern conifer treeline on the Kola Peninsula of Russia illustrates this point (Gervais et al., 2002; MacDonald et al., 2000a). The wood megafossil record (Figure 5) suggests the establishment of Scots pine at the site at about 7400 cal years BP (6500 ^{14}C years BP). In contrast, the fossil pollen record shows an earlier large increase in *Pine* pollen, commencing at about 8200 cal years BP (7500 ^{14}C years BP). Studies on the Kola Peninsula have shown that *Pinus* conifer stomata preserved in lake sediments can provide a relatively spatially precise indication of the position of treeline, as such stomata initially arrive in the lake on needles which are likely not to be transported far from the tree (Gervais and MacDonald, 2001). The stomata record from the same lake indicates that Scots pine was established around the lake by 8.8 cal ka BP (8000 ^{14}C years BP) – significantly earlier than is indicated by the wood megafossil record. Although lags between the megafossil record and the palynological record are not universal – and in some cases megafossils can yield similar or earlier arrival dates than palynological records (Barnekow, 1999; Kullman, 1998a; 1999) – care should be taken in implying a maximum age for the presence of a species based upon the megafossil record alone.

Studies From Selected Regions

Tuktoyaktuk Peninsula

Surface finds of spruce wood have been reported from north of the modern treeline in Tuktoyaktuk Peninsula region of Canada (Figure 6). Wood has also been found in exposures of organic sediments. The wood samples come from sites that extend as far as 40 km north of the modern limits of spruce. The samples range in age (Table 1) from ~7500 to 5600 cal years BP (6600–4900 ^{14}C years BP). The magnitude of the range extension of spruce trees beyond their modern limits, and comparison of the tree-ring widths of the fossil wood with the ring growth rates of living spruce trees to the south, suggest that summer temperatures on the Tuktoyaktuk Peninsula were as much as 3 °C warmer during the early to mid-Holocene than today. The ages of the spruce megafossils correspond with fossil pollen evidence from lakes on the peninsula that show markedly increased amounts of spruce pollen during the early to mid-Holocene (Ritchie, 1984; Spear, 1983).

Northern Quebec

Wood megafossils have been used in a number of studies to investigate the age and dynamics of treeline forest and krummholz populations of spruce in northern Quebec. In many cases, these studies have focused on using megafossils cross-dated with living trees to extend dendrochronological records of climate change and ecological response (e.g., Wang et al., 2001). In other cases, wood megafossils have been used in concert with radiocarbon-dated charcoal from soils which is

Figure 5 A comparison of evidence for the arrival of *Pinus sylvestris* on the northern Kola Peninsula based on *Pinus* pollen, wood megafossils, and *Pinus* stomata. (Data from Gervais et al., 2002)

indicative of past forest presence and fires. Dated megafossils indicate that spruce trees arrived in the vicinity of the present treeline by 5000 cal years BP. There is also megafossil evidence of several minor readvances in treeline or infilling of the tree-line zone following 3000 cal years BP (Arseneault and Payette, 1997). The older megafossils in this region appear to be present in peats.

Fennoscandia–Kola Peninsula

Radiocarbon-dated and dendrochronologically dated wood macrofossils have been reported from a number of high-latitude and high-elevation tundra sites in Fennoscandia and the adjacent Kola Peninsula of Russia. Megafossils of *Pinus sylvestris* beyond its present species' range limits are particularly common and have long-provided evidence (Eronen, 1979) that pines grew both higher in latitude and higher in elevation during the early to mid-Holocene (Figure 7). The abundance of *Pinus sylvestris* wood has allowed for the development of a >7000 year tree-ring chronology for Finnish Lapland (Eronen et al., 2002; Zetterberg et al., 1996). Much of the wood for that chronology was retrieved from lakes. The abundance of drowned trees in lakes was combined with other evidence to infer that conditions in northern Fennoscandia were drier than present between 8000 and 4000 cal years BP (Eronen et al.,

1999). Indeed the rising water levels during the latter part of the Holocene likely played a role in the preservation of abundant wood megafossils in the small lakes of the region.

Some of the most remarkable reports of megafossil wood come from the south in the Scandes Mountains of Sweden (Table 2). Megafossils of *Pinus sylvestris*, *Picea abies*, *B. pubescens*, and other woody species have been found well above their modern range limits and dated to as far back as the early Holocene and Late Glacial (e.g., Kullman, 1998a,b, 1999, 2004). *B. pubescens* wood has been recovered from melting snowbanks and glaciers as much as 650 m above the present elevational range limits of the species, indicating a much higher treeline for birch between 9700 and 7000 cal years BP (8700 and 6200 ¹⁴C years BP). It has been estimated that summer temperatures were likely 3 °C warmer than present during this time period (Kullman, 2004). Another remarkable detail of the finds in the Scandes Mountains is the occurrence of *L. sibirica* wood dating from the early Holocene (Kullman, 1998b). Today, the species does not occur naturally in Fennoscandia. The presence of *Larix* in Fennoscandia during the early post-glacial implies both rapid rates of range expansion at the close of the last Ice Age and the development of a vegetation that has no modern analog in the region. Intriguingly, *Larix* pollen has not been found in regional sedimentary records, and there is vigorous discussion about the dates and interpretation of some

Figure 6 *Picea* megafossil locations and radiocarbon dates from the Tuktoyaktuk Peninsula, Canada. (Data from Ritchie, 1984).

Table 1 Ages of dated *Picea* wood from the Tuktoyaktuk Peninsula, Canada

of the early Holocene and Late Glacial megafossil finds from the Scandes (Birks et al., 2005; Kullman, 2005).

Higher-frequency climatic changes and forest response are also evident in the wood megafossil records of Fennoscandia and the adjacent Kola Peninsula. For example, warmer summer temperatures during AD 1000–1300 (coeval with the 'Medieval Warm Period' observed in other parts of Europe) are evident in a megafossil stumps from the Khibiny Mountains of the Kola Peninsula which indicate a 100–140 m upward shift in the *Pinus sylvestris* limit compared to today. Rooted stumps of *Pinus sylvestris* from a small pond suggest drier conditions during the same period (Kremenetski et al., 2004).

Northern European Russia and Siberia

As mentioned earlier, there is a long history of scientific investigation of wood megafossils from the tundra regions of the

Russian Federation. Aside from the finds of *Pinus sylvestris* from the Kola Peninsula which were discussed earlier, wood from *Pinus*, *Picea*, *Larix*, and *Betula* has been reported from sites extending eastward to the Polar Urals and thence onward to the Chukotka region in the far east of the Russian Federation (Khotinsky, 1984; Kremenetski et al., 1998; MacDonald et al., 2000b). Many of the samples recovered thus far come from surface finds or fallen and *in situ* stumps that can date back to the early to mid-Holocene. Wood has also been recovered from organic soil exposures, exposures of colluvium, cut-banks along river and stream channels, and from small lakes. A broad synthesis of the many available dates suggests that boreal trees were present at or beyond their modern range limits across northern Eurasia by about 11400 cal years BP (10000 ^{14}C years BP). Between the period 10000 and 3200 cal years BP (9000 and 3000 ^{14}C years BP), the range limits of boreal trees extended north of their modern ranges in most regions, reaching the current Arctic coastline in some areas (Figure 8).

	<i>Betula pubescens</i>	8190 $\pm$ 90	9072–9144	Beta-96581

Data from Kullman L (1998) Palaeoecological, biogeographical and palaeoclimatological implications of early Molocene immigration of *Larix sibirica* Ledeb. into the Scandes Mountains, Sweden. *Global Ecology and Biogeography Letters* 7: 181–188.

The range extension was over 100 km in some instances, and summer temperatures were likely at least 2.5 °C warmer than present (MacDonald et al., 2000b). In some regions such as central Siberia it is possible that summer temperatures were

as much as 5–7 °C warmer than present. Between 4500 and 3200 cal years BP (4000 and 3000 ^{14}C years BP) there was a seemingly synchronous retreat of treeline to near modern positions.

Figure 8 Holocene treeline advance and retreat from northern Russian Eurasia based upon wood megafossils. Reproduced from MacDonald GM, Velichko AA, Kremenetski CV, et al. (2000) Holocene treeline history and climate change across northern Eurasia. *Quaternary Research* 53: 302–311.

The abundance of megafossils in portions of northern Siberia allow for multicentennial tree-ring records to be produced (e.g., Shiyatov et al., 1996). Recently, for example, a detailed dendrochronological and radiocarbon-based study of subfossil *L. sibirica* megafossils was reported from the southern edge of the Yamal Peninsula in western Siberia (Hantemirov and Shiyatov, 2002). That study produced a remarkable 4000-year-long dendrochronological record. Most of the surface finds in the region date back only about 750 years, but older megafossils are abundant in river bank exposures. The abundance of wood and documented presence of additional wood, dated at more than 9000 years old, provide the possibility of developing a Holocene length record of tree-ring-based summer temperature estimates from the region.

Introduction

Dendrochronology, the science of tree-ring dating, is the most accurate and precise nondocumentary dating method available to researchers studying terrestrial records of the recent past. Tree-ring dates are accurate and precise to the year, and sometimes season, and have no associated statistical uncertainty or standard error. All other archaeological dating techniques that use natural materials (e.g., radiocarbon and archeomagnetism) have been calibrated using dendrochronological samples (Struiver, 1978). It is this precision and accuracy that has allowed dendroarchaeologists to construct detailed cultural chronologies in many parts of the world, and to explore a plethora of environmental, social, and behavioral questions regarding past human adaptations.

Developed in the early twentieth century by Andrew Ellicott Douglass (Figure 1) in the southwestern US (Nash, 1998; Webb, 1983), dendrochronology is probably best known as a technique that provides absolute Christian calendar dates for archaeological sites in the US southwest. Dendroarchaeological dating has been used to date sites, structures, artifacts, and such cultural phenomena as phases and periods (Dean, 1996). Dendroarchaeological is practiced in many areas, but is used most in the US southwest due to factors of history and preservation.

Tree-Ring Requirements

Trees must exhibit four attributes in order to be dendrochronologically useful (Fritts, 1976, 1991). First, they must produce distinguishable annual growth layers (rings) (Figure 2). Second, an individual ring must grow in a uniform manner around the bole of the tree, or branch (i.e., it must exhibit circuit uniformity). Third, the rings must exhibit some type of annual variability, such as ring width, ring density, etc. Finally, a sample must contain a sufficient number of rings to permit the identification of variability patterns; in southwestern conifers, 50–100 rings are usually sufficient; in other areas and with other species like European oak, 200+ rings may be necessary (Baillie, 1982).

The most fundamental principle of dendrochronology is crossdating — matching patterns of annual variability among local or regional tree populations (Douglass, 1941). In the US southwest, the skeleton plot method of crossdating has been used successfully for decades. Dendrochronologists in eastern North America, Europe, and the Middle East who examine angiosperms, however, use a quantitative method of crossdating, based on precise ring-width or ring-density measurements (Baillie, 1995). Both methods work equally well in their respective areas. If the variability patterns on a sample do not exactly match the tree population, the sample does not cross-date and cannot be used in dendrochronology. In this critical

respect, crossdating is fundamentally different than counting rings or estimating tree age.

Crossdating allows dendrochronologists to assign a single calendar year to each and every ring on a sample, but not all trees or archaeological samples produce dates. Some trees produce cambium in response to microenvironmental factors that are not reflected in the tree population; others respond to nonclimatic factors such as nutrient availability; and still others do not produce annual rings.

In order to construct a chronology, the skeleton-plotted samples from living trees, standing snags, remnant wood, and archaeological samples are combined into a master skeleton plot (Stokes and Smiley, 1968). By overlapping the plots of individual specimens, the chronology can be extended backwards in time (Figure 3) until a lack of sample depth precludes crossdating. Specific small ‘marker rings’ that occur on a large proportion (usually >75 percent) of samples in a collection help establish the basic pattern which is then tested against additional samples and nearby chronologies. In addition to small size, marker rings may be identified by internal features such as frost-damaged cells, false or double rings, unusually wide or narrow latewood bands, or other microscopically visible attributes.

Dendroarchaeological Date Attributes

Even when samples produce dates, they must still be interpreted, and not all archaeological tree-ring dates are the same. Because dendroarchaeological samples are the result of past human behaviors, specific sample attributes and the archaeological context must be considered in any interpretation of the chronological materials. Sample attributes can be used to identify cutting, near-cutting, and noncutting tree-ring dates.

Cutting dates, also known as tree-death dates, retain the last cambial layer grown by the tree and indicate that the tree was cut in a specific year (assuming tree death resulted from human harvesting). Evidence on the sample that it is a cutting date includes the presence of bark, beetle galleries, a shiny patina, or a continuous ring around the sample (Ahlstrom, 1985; Towner, 1997). In the literature, the cutting date is denoted by the symbol ‘v,’ — noting that in the opinion of the analyst, the last ring on the sample is the last ring grown by the tree.

Samples that retain the last cambial layer can also be assigned a cutting (death) season. Those that exhibit a terminal ring with a full complement of latewood were cut after the growing season for that particular year. Samples that show only earlywood cells were cut during the growing season. Because different tree species have different growing seasons, cutting dates in a structure in the same year from different species can confine construction to a relatively small time period, as little as 4–6 weeks in some cases (Dean and Warren, 1983; Towner and Dean, 1992).

Samples that yield near-cutting dates also retain the last ring grown by the tree; however, these particular samples may (or may not) contain a locally absent or missing ring near the end of the sample ring sequence, and are denoted by a '+' symbol (Ahlstrom, 1985; Towner, 1997). There is no way to verify the absence (or presence) of the missing rings near the end of the ring sequence, so near-cutting dates should be considered within a year or two of tree-death dates.

Noncutting dates result from two different processes: exterior ring loss or ring counts near the outside of the sample ring

sequence (and are denoted by 'vv' or '++', respectively) (Ahlstrom, 1985; Bannister, 1962; Haury, 1935). Samples that do not retain the last ring grown by the tree (vv dates) have suffered exterior ring loss either through natural processes such as erosion, or cultural processes such as beam shaping. Thus, a sample dated AD 790–957 vv could not have been cut prior to AD 957, but because it may be missing one, 10, or even 100 exterior rings, the harvesting date cannot be determined with any degree of confidence. Partially ring-counted specimens (++ dates) result from a lack of crossdating on the sample beyond a specific year. Ahlstrom (1985) suggests that ++ dates may indicate deadwood use because as trees die a slow natural death, they respond less and less to macroenvironmental conditions and produce more sporadic cambial growth layers. Noncutting dates (both vv and ++) provide only a *terminus post quem*, a date before which tree death could not have occurred; a noncutting date may predate the actual use of a beam by years, decades, or even centuries.

Dendroarchaeological Sampling and Sample Preparation

Dendroarchaeological samples may be collected in several different ways. Most commonly, they are recovered as charcoal pieces during excavations. Such specimens need to be handled gently during transport to the laboratory. They should be wrapped in cotton batting and string to protect them, but need no special stabilization. Another common method is extracting cores from intact beams (Figure 4), using a specially made drill bit similar to an elongated hole saw. The resulting cores ($\frac{1}{2}$ –1" diameter) retain the rings in the beam, although they may exhibit more locally absent rings than cross sections due to their small size. Finally, dendroarchaeological wood samples can be collected as loose pieces or cut into cross sections, but such techniques have a greater impact on the archaeological record.

After transport to the laboratory, dendroarchaeological samples are prepared for analysis under the microscope. Charcoal specimens require no surfacing and are simply broken to expose a fresh surface. Wood samples are sanded with increasingly finer grit sandpaper, sometimes up to 500 grit, to expose the individual cells and ring structure. All samples are then examined under a binocular microscope at 10–40× power.

Chronological Information from Dendroarchaeological Samples

The keys to determining when a room, site, or artifact was constructed are: (1) identifying date clusters; and, (2) explaining anomalous dates. Identifying anomalous dates requires (1) an adequate sample of dates and (2) defining date clusters. An adequate number of dates is a relative term that depends on the number of samples available for collection, the number of samples collected, and the number of dates derived. Single dates provide limited information of any kind. Ahlstrom (1985) has defined a date cluster as 'three or more dates falling in a brief time interval,' but definitions vary among researchers and from collection to collection. Ahlstrom has adapted the stem-and-leaf technique to plotting tree-ring dates in order to provide a detailed visual representation of each date in a distribution. Applying the technique to archaeological tree-ring dates, he identified an 'ideal' date distribution as a single line on the plot consisting of entirely cutting dates in the same year (Ahlstrom, 1985). The author enlarged this concept (Figure 5) and proposed that different date distributions could be used to identify different wood-use behaviors. Although stem-and-leaf plots separate the dates from their archaeological contexts, they delineate the temporal attributes of samples and allow an initial assessment of the relationships among them. Because the stem-and-leaf technique ignores the archaeological context of tree-ring dates, however, it does not fully explain past human behavior. It is important to note, however, that although the tree-ring dates are precise and accurate, it is the

Figure 5 Idealized histograms of different wood use behaviors.

archaeological context and interrelationships between samples and date clusters that facilitates behavior interpretations.

Environmental Information from Dendroarchaeological Samples

The precise chronological data provided by tree-ring dates — even well provenienced cutting-date clusters — illuminate more than simply the temporal aspects of an occupation.

Embedded in the samples is also important environmental information which can be derived from dendroarchaeological samples in two ways. First, the tree species exploited by past peoples may indicate aspects of local species availability and thus, environmental composition. Second, dendroarchaeological samples can be used to reconstruct past precipitation and/or temperature regimes and identify past 'extreme' climatic events.

The tree species present in archaeological tree-ring collections are the result of several factors. First, site occupants often

exploited the most available species; thus, archaeological samples can be used to assess past species distributions and forest composition (at least at the 'generic' level). For example, the Black Mesa Archaeological Project (BMAP) in northern Arizona collected more than 5000 tree-ring samples from Navajo archaeological sites that were occupied between 1800 and 1972 (Dean and Russell). The modern vegetation community of Black Mesa consists predominately of pinyon-juniper forest, isolated stands of ponderosa pine and Douglas-fir, and various nonconiferous species. The Navajo BMAP dendroarchaeological samples mirror this distribution both in terms of species availability and spatial distribution, that is, in areas with higher concentrations of one species, that species was most often used in structure construction (Dean and Russell). These data indicate little ecological change in the composition of Black Mesa forests over the past 200 years.

Species distributions in archaeological collections are affected by more than species availability, however. Human social and economic systems also affect the presence and proportions of species in collections. The example below demonstrates the influence of human tree selection that does not reflect local environmental variability.

Bonde and Christensen (1993) have dated several Viking ships built with oak timbers that demonstrate the impact of economic systems on the species distribution in archaeological sites from northern Europe. The sunken ships are located in Scandinavia, primarily Sweden and Denmark, but do not crossdate with local tree-ring chronologies. Through comparisons with several other northern European oak chronologies, Bonde and Christensen (1993) identified the source of the ship timbers as northern Ireland. They suggest that whereas ship-building was conducted in Denmark, the raw materials for construction were imported from across the North Sea, a process that certainly required significant organizational and technological skills.

Dendroclimatic Analyses

Climatic and cultural information inherent in archaeological tree-ring samples have been linked since the 1930s. When Douglass 'bridged-the-gap' between his modern and archaeological chronologies, it became apparent that the 'Great Drought' of the late 1200s in western North America had caused difficulties in crossdating because of many missing and microrings during the AD 1270–1300 period (Douglass, 1935; Nash, 1997). The cliff dwellings of Mesa Verde and other sites in the Four Corners area were abandoned at about the same time, which also significantly reduced the sample size available for analysis. The temporal correlation between the drought and abandonment suggested to many archaeologists a causal relationship between the former and the latter.

Since Douglass' early efforts, the use of dendroarchaeological samples to examine past environmental variability has contributed significantly to our understanding of past human-environment interaction (Dean et al., 1985; Van West, 1994). The low-elevation conifers found in most southwestern archaeological sites, including pinyon pine, juniper, Douglas fir, and ponderosa pine, typically respond to moisture (Fritts, 1991) and, therefore, precipitation reconstructions have been developed for much of the area.

In general, two different types of dendroclimatic studies have been conducted using dendroarchaeological samples: qualitative and quantitative. Qualitative studies use tree-ring chronologies as a direct measure of the relative variability in past climates; such qualitative reconstructions provide accurate indications of the relative deviation of annual precipitation (Dean and Robinson, 1977). Quantitative reconstructions require modern environmental data by which to calibrate tree growth and rigorous statistical testing to validate the results. Quantitative reconstructions use mathematical models to define the relationship between tree growth and specific environmental parameters, and statistically estimate the past variability of the environmental factors, such as inches of rainfall, degrees of temperature, etc. Such estimates are typically smoothed to identify long-term trends, but can be presented as annual or even seasonal values (Fritts, 1991).

These brief examples demonstrate the value of dendroarchaeological samples for eliciting information about past environmental conditions. By their very nature, dendroarchaeological samples also contain information about past human activities. It is a goal of dendroarchaeology to combine these data sets to further our understanding of how past peoples adapted to and modified their environments.

Behavioral Information from Dendroarchaeological Samples

The key to deriving behavioral information from dendroarchaeological samples is the identification of anomalous dates. Anomalous dates are defined as those dates that do not date the event of interest (Dean, 1978) and are therefore dependent upon the archaeological context and research question. The tree-ring dates themselves are precise and accurate; they date the last ring on the sample, but may not date the event of interest. For example, if one is interested in dating the construction of Balcony House in Mesa Verde, Colorado, one of the most visited cliff dwellings in the world, the 1910 cutting date from Room 3 is clearly anomalous. If on the other hand, the event of interest is dating the stabilization work of Jess Nusbaum, the 100+ dates in the AD 1200s are considered anomalous (Parks and Dean, 1990). Obviously, dates are only anomalous within a context, and all dates may be anomalous in different contexts.

The behavioral information inherent in archaeological tree-ring samples is directly affected by two major factors: the behavior of past peoples and the behavior of archaeologists and dendrochronologists. Past peoples must have: (1) used wood as a resource for building structures, making artifacts, and as fuel; (2) they must have exploited species that are appropriate for dendrochronological analysis; and, (3) they must have used wood in ways that insured its preservation in the archaeological record. Archaeologists influence tree-ring data by: (1) selecting sites for study that contain dendrochronological materials, (2) precisely recording the provenience and surface attributes of samples, and, (3) properly collecting and submitting the samples for analysis. Dendrochronologists must correctly date the samples and describe their microscopic attributes, i.e., terminal ring characteristics, false and microrings, etc.

Certainly, the above-described species selection and economic procurement systems represent past human behaviors. It is at the individual beam, room and structure, and site level, however, that most detailed human behaviors can be identified. Such behaviors include species-selection preferences, deadwood use, beam stockpiling, beam reuse, structure repair and remodeling, structure abandonment, and beam harvesting, preparation, and modification. When data from many beams, rooms, and sites are combined, it is possible to identify broad-scale patterns of how specific groups treated wood as a resource.

This is one area where dendroarchaeology differs from other subfields of dendrochronology. Single samples or site collections are related to specific past human activities and may not contain information relative to larger spatial and temporal issues. For example, the collection and analysis of 130 high-altitude bristlecone pine specimens from the San Francisco Peaks of northern Arizona has had important ramifications for reconstructing temperature variability in the entire Southwest and across western North America for the past two thousand years (Salzer, 2000). In contrast, the collection of 4294 archaeological samples from Pueblo Bonito in Chaco Canyon informs us about the activities of a specific group of people in a specific time and place (although environmental information is contained in those samples as well) (Windes and Ford, 1996). Dendroarchaeological specimens are part of a specific human behavioral context that may (or may not) be directly related to broader patterns.

The first level of analysis for illuminating past human behaviors is at the individual beam level. Precise provenience and sample attribute information can reveal aspects of beam function, procurement, and preparation. Beam function includes information about the architectural element and its use, such as a roof primary or secondary beam, and a door lintel or jamb. In many cases, specific species and sizes may have been preferred for specific architectural elements (cf. Dean and Warren (1983) and Windes and Ford (1996)). Beam procurement methods include cutting with various types of stone or metal axes or saws, breaking, or burning. Noting the procurement method on a sample may indicate the use of deadwood (breaking, burning) or provide a temporal framework for undated samples (i.e., different saw marks relate to technological innovations in saw technology). Beam preparation may include removing limbs, bark, shaping a beam, and preparing the beam ends using various tools. Beam preparation tools include various types of axes and saws as well as draw knives, axes, and grinding tools. Identifying the types of tools used to procure and prepare timbers may have implications for interpreting anomalous dates, distinguishing technological traditions, or recognizing cultural interaction.

At the room and structure level, it is necessary to document the architecture as completely as possible. Such characteristics as the bond-abut relationships of walls, changes in wall construction materials or plastering, changes in room function denoted by sealed doorways or covered hearths, and other architectural attributes can help in determining when the room was built (as opposed to when the beams were harvested) and provide clues to the nature of the occupation. When combined with beam attributes and dates, such information can help to identify anomalous dates, the use of

deadwood, the reuse of older beams from other rooms or sites, the stockpiling of beams, the repair and remodeling of rooms and structures, and can yield information relative to the duration of occupation and mode of abandonment of a room or structure. These combined data can help illuminate aspects of human social organization, such as the use of a room or structure by a family or supra-family group; they may also contribute to understanding the dynamics of that group through time, such as changing structure use in response to generational changes in family size, the immigration of new families into a settlement, and many others.

At the site and regional levels, dendroarchaeological data provide the temporal control necessary to delineate broad patterns of human behavior. At the site level, the initial founding of a site can often be determined through tree-ring analysis, and the duration of the occupation may also be delineated. An excellent example of the former is Douglass' dating of the Mesa Verde cliff dwellings (Douglass, 1929). Prior to the advent of dendroarchaeology, archaeologists debated whether the structures were hundreds or thousands of years old. Douglass' precise dating of these ruins to the thirteenth century had profound implications for archaeological and anthropological theories of the rate of human cultural development in the New World. Similarly, before large-scale sampling efforts and detailed analysis documented the duration of occupation of the Kayenta Anasazi cliff dwelling of Betatakin at less than 40 yr (Dean, 1969), many people assumed such structures had been occupied for hundreds of years. Again, such temporal compression has required anthropologists to reexamine their theories of cultural evolution, and has forced archaeologists to consider the importance of settlement mobility patterns in interpretations of population demographics and history.

At the regional level, dendroarchaeological data contribute to understanding population dynamics, culture change, and interaction in a variety of ways. For example, recent dendroarchaeological analysis of several Navajo pueblito structures in Palluche Canyon, New Mexico, reveals very similar initial construction, remodeling, and abandonment dates (Ababneh et al., 2002). These small three to five room structures were all apparently constructed, temporarily abandoned, reoccupied, and finally abandoned within a period of about 20 yr. The archaeological and dendrochronological data suggest all the sites were occupied by the same extended family group, and this inference is supported by ethnographic data and Navajo oral traditions (Ababneh et al., 2000). Thus, these sites can now be related to a specific period in Navajo history, a specific form of social organization, and perhaps to a particular descendent group of Navajos.

On a larger scale, dendroarchaeological data have been used to illuminate aspects of significant migrations both during the prehistoric period and during the early historic period. Recently, the author has suggested that the Navajo immigration out of their Dinétah homeland in northwest New Mexico and into northeastern Arizona during the 1700s was a social and economic process unrelated to the single-year drought of 1748 (Towner, 2003). These large databases enable archaeologists and dendrochronologists to investigate important questions concerning how humans, as individuals, families, and supra-family groups, colonized landscapes, exploited

their environments, interacted with their neighbors, and responded to changes in their physical, social, and technological environments.

Conclusions

Dendroarchaeology is a powerful tool for studying the recent past, but it has certain limitations. As noted above, the two most important factors in dendroarchaeological research are the behavior of past peoples toward wood as a resource and the behavior of archaeologists and dendrochronologists. Fortunately, the US southwest was occupied by groups who used those tree species to build structures, make artifacts, cook, and heat their homes. In some areas, such as the extreme deserts of North and South America, North Africa, and Australia, people simply did not use wood (or did not use dendrochronologically useful species). Dendroarchaeological research in those areas may be extremely limited. Even in areas with appropriate tree species, past human behavior still constrains the application of dendroarchaeology. For example, the longest archaeological tree-ring record in the southwest extends back only to 323 BC. This limit is not imposed by tree species or preservation, but results from the fact that Archaic period populations did not build substantial structures or use large conifer beams for fuel.

The most important factor in the success or failure of dendroarchaeological research in a given area is institutional support. The Southwest, the United Kingdom, Germany, France, and Switzerland have been in the forefront of dendroarchaeological research for decades simply because they have had well-qualified dendrochronologists and funded research programs. The importance of such programs cannot be overstated.

Dendrochronology is the most precise dating method available to scientists studying the recent past. Dendroarchaeology is best known as a technique that provides Christian calendar dates for large archaeological sites. Dendroarchaeology is much more than simply a chronometric technique however; it also provides data relevant to understanding past environmental conditions and change, as well as information important for illuminating aspects of past human behavior at various spatial scales. When these chronological, environmental, and behavioral data are combined, dendroarchaeology can help illuminate aspects of past human interaction with the physical, social, and technological environments.

This article is reproduced from the previous edition, volume 3, pp. 2315–2336, © 2007, Elsevier B.V.

Introduction

The potential scope of ‘mire and peat macrofossils’ is enormous, given both the substantial range of plant macrofossils preserved in peat sequences and the ~400 million hectare global extent of peat deposits (Barber and Charman, 2003). Peat is defined as accumulated sediment which contains at least 30% dry mass of dead organic material, and mires as peatlands where peat is currently being formed. Therefore this article is focused on Holocene northwest European raised peat bog (ombrotrophic) and fen (minerotrophic peatland) deposits (see Wheeler and Proctor, 2000, for a detailed review of peatland terminology), subjects in which the authors have greatest expertise and experience. In this article, how mire and peat macrofossil analyses have been used to investigate Quaternary environmental change, and the methodologies used to prepare and analyze the samples are discussed. A review of the paleoecological indicator value and identification notes of a representative selection of mire and peat plant macrofossils forms a major part of this article. We include a series of photographic figures as an aid to macrofossil identifications. It is certainly not a comprehensive selection, but serves to extend and complement the identification keys and photographs/illustrations currently available. The figures will not only be of value to paleoecological analyses of mire and peat macrofossils in northwest Europe. Some of the species we describe here have also been recovered from peatlands in southern Québec, Canada (Pellerin and Lavoie, 2003); the Western Great Lakes Region, USA (Booth et al., 2004); Tierra del Fuego, Argentina (Mauquoy et al., 2004a); and the East-European Russian Arctic (Välranta et al., 2003).

Applications

Environmental change reconstructions based on mire and peat macrofossil analyses are limited, in that full plant assemblages cannot be reconstructed and directly compared with detailed neophytosociological studies. This problem occurs due to the selective nature of vegetation decomposition in peatlands, since even decay-resistant *Sphagnum* mosses have different decomposition rates (Johnson and Damman, 1991). Due to the potential for differential preservation and representation of the bog vegetation, successional and/or paleoclimate reconstructions produced from subfossil assemblages need to be interpreted cautiously. Furthermore it is not always possible to identify *Sphagnum* spp. to the lowest taxonomic level, particularly where their stem leaves are absent. Cyperaceous (sedge and allies) remains are also difficult to identify consistently, since in many instances seeds and diagnostic epidermal tissues are simply not present.

Subfossil plant macrofossils preserved in peat samples have been used to reconstruct Holocene raised peat bog vegetation

succession at microform scales (analyses of a single borehole to reconstruct vegetation changes in hummock/hollow microform complexes see McMullen et al., 2004; van der Molen, 1988; van Geel, 1978) and mesoform scales (transects of boreholes analyzed across single raised peat bogs see Barber et al., 1998; Hughes et al., 2000; Svensson, 1988). The aim of much of this research on ombrotrophic (rain-fed) peat bog stratigraphy has been paleoclimate reconstructions, since changes in bog surface wetness recorded by plant macrofossils are highly likely to represent changes in precipitation and temperature (Barber and Charman, 2003; Barber et al., 2004). The macrofossil data produced from this research are equally valuable in peatland carbon accumulation rate studies (Oldfield et al., 1997) and the identification of successional processes in peatlands, for example, the nature and timing of the fen/bog transition (Hughes and Barber, 2004). Applied paleoecological research using plant macrofossil data has provided long-term baseline data for the origin and nature of vegetation changes, which can be used to guide conservation management in environmentally sensitive areas (Chambers et al., 1999). The nature and timing of recent human disturbance to ombrotrophic bogs, for example burning and drainage, has also been assessed (Pellerin and Lavoie, 2003). Dating peat samples using ^{14}C accelerator mass spectrometry has now become the standard method, and it offers the possibility of dating above-ground parts of identified plants, for example, *Sphagnum* leaves or fruits of *Rhynchospora alba*. This is highly advantageous, since cyperaceous roots and the stem bases and attached lower parts of *Eriophorum vaginatum* leaves can be avoided. These have been shown to be younger (because of downward growth) than bryophyte fragments in the same ^{14}C -dated stratigraphic levels (Kilian et al., 2000). Plant macrofossil expertise can be used to pinpoint the best samples possible (above-ground macrofossils, preferably free of fungal contamination) for ^{14}C -dating peat sequences in order to create accurate and precise chronologies (Mauquoy et al., 2004b).

Methods

Analyses of plant macrofossils in peat deposits requires samples of ~5 cm³, and these can be recovered using a 7- or 9-cm diameter ‘Russian’ pattern corer, a Wardenaar peat sampler (to a maximum depth of 1 m), or where peat sections are exposed, 50 (100) × 15 × 10 cm metal boxes can be used. Analyses of the field stratigraphy of the peat bog (Barber et al., 1998) is highly desirable prior to taking the master core that will be subjected to detailed paleoecological analyses. This can be undertaken using a 5 cm diameter ‘Russian’ pattern corer (either 50 or 100 cm length). When sampling a ‘living’ peat bog, care should be taken to avoid compression of the surface layers of the peat deposits. Before subsampling, 5 mm of peat from the core should be trimmed to avoid contamination and

only clean instruments used to avoid the introduction of 'modern' carbon and/or contamination with older or younger macro/microfossils.

Plant macrofossil samples should be gently boiled with 5% KOH (deflocculation to dissolve humic and fulvic acids) and disaggregated. When sieving (on a 125 or 150 µm sieve) the plant remains must be kept just under the water surface (to avoid too much damage of delicate subfossils, e.g., *Sphagnum* stems with their stem leaves still attached). Stem leaves can be very important for *Sphagnum* identification, because they can help considerably in identification to species level. Macrofossils retained on the sieve are then transferred to a petridish and only enough distilled water should be added to float the remains, which are scanned using a low power ($\times 10$ –50) stereo zoom microscope. Moss leaves, cyperaceous epidermal tissues, and small seeds (*Juncus* spp.) need to be mounted onto temporary slides and examined at high magnifications ($\times 100$ –400).

Reference collections are essential in aiding and confirming the identification of mire and peat macrofossils. Above-ground (leaves, stems, flowers, fruits, and seeds) and below-ground (rhizomes and roots) parts of peatland plants can be collected during fieldwork or from a herbarium. The best reference collection, however, is one derived from fossil remains (Grosse-Brauckmann, 1986), where the identifications have been confirmed by an experienced analyst.

A range of techniques are available to present the data. The simplest technique is to use ordinal values, for example, 1 = rare, 2 = occasional, 3 = frequent, 4 = common, and 5 = abundant (Barber, 1981). Alternatives to this are to make quantitative estimates using volume percentages (see the quadrat and leaf count macrofossil analysis technique widely adopted by Barber and Charman (2003)) or absolute numbers, calculated as either concentrations (number of objects per unit volume, Booth et al., 2004; Janssens, 1983) or influx (based on age-depth models). All three techniques can be combined to present different macrofossil components from a single peat sequence, for example, mosses, dwarf shrubs, and cyperaceous roots can be expressed as percentages; bark, wood, and bud scales as ordinal values; and seeds as absolute numbers (Välranta et al., 2003).

Macrofossil Indicator Value and Descriptions of Northwest European Mire and Peat Macrofossils

Calluna vulgaris

Hammond et al. (1990) investigated the position of *Calluna vulgaris* (Figure 1(a)–1(f)) in relation to local raised peat bog water tables, and found that it occurred under minimum and maximum water table depths of 10 cm and 52 cm, respectively, with 90% of occurrences at 30 cm water table depth. It is restricted to drier microforms, because the roots and their endomycorrhizas need an aerated layer about 10–20 cm deep (Lindholm and Markkula, 1984).

Erica tetralix

Erica tetralix (Figure 1(g)–1(k)) can withstand some waterlogging under experimental conditions (Bannister, 1964). Hammond et al. (1990) investigated the position of *Erica*

tetralix in relation to local raised peat bog water tables and found that it occurred under minimum and maximum water table depths of 5–52 cm below the surface, with 90% of its occurrences recorded at sites with a 35 cm water table.

Empetrum nigrum

Empetrum nigrum (Figure 1(l)–1(o)) is intolerant of prolonged waterlogging and is restricted to well-drained hummock microforms on raised peat bogs (Bell and Tallis, 1973) and can occur abundantly in mire margins (Økland, 1990).

Andromeda polifolia

The highest shoot frequencies of *Andromeda polifolia* (Figure 2(a)–2(d)) occur in raised peat bog low hummock and lawn microforms (Lindholm and Vasander, 1981). It can extend into wet hollow microforms, but does not occur in the wettest locations (Jacquemart, 1998).

Vaccinium oxycoccus (*Oxycoccus palustris*)

Growth of *Vaccinium oxycoccus* (Figure 2(e)–2(g)) is optimal where average groundwater levels are 25–30 cm below the root–stem junction (Gronskis and Snickovskis, 1989). It occurs predominantly in moist hollow microforms on raised peat bogs (Lindholm and Vasander, 1981).

Drosera

Drosera spp. (Figure 2(i) and 2(j)) are insectivorous, short-lived herbaceous perennials of open, oligotrophic bogs. The seeds of *Drosera rotundifolia* and *Drosera anglica* are similar but strongly differ in morphology from *Drosera intermedia* seeds.

Eriophorum vaginatum

Eriophorum vaginatum (Figure 2(k)–2(m)) can grow over a large range of moisture conditions, and forms a dominant component of peat communities that experience surface water levels in the spring and subsequent reduced water levels in the summer (Wein, 1973). Drought conditions are not unduly harmful, as the species can survive due to its deep-rooting habit, since the rhizomes may extend to 60 cm below the surface (Gore and Urquhart, 1966). *Eriophorum vaginatum* is capable of invading pools, and paleoecological evidence supporting this observation, has been presented by Barber (1981). Hammond et al. (1990) most frequently encountered this species in peat with a water table at 24 cm depth, although it had a range spanning 0–28 cm, which demonstrates its wide tolerance to water table depth. Økland (1989, 1990) also concluded that it was 'ubiquitous and omnipresent,' although it was less common in carpets and low lawn microforms.

Eriophorum angustifolium

Godwin and Conway (1939) describe *Eriophorum angustifolium* (Figure 3(a) and 3(b)) as a species which characteristically colonizes drying pools. In a similar manner to *Eriophorum vaginatum*, the well-protected stem apex of *Eriophorum*

Figure 1 (a)–(f) *Calluna vulgaris*: (a) remains *in situ*; (b) stem with flower; (c) leaf epidermis; (d) twig without leaves; (e) stem; (f) seed. (g)–(k) *Erica tetralix*: (g) stems and leaves *in situ*; (h) leaf; (i) leaf epidermis; (j) and (k) seed. (l)–(o) *Empetrum nigrum*: (l) and (m) leaves; (n) leaf epidermis; (o) seed.

Figure 2 (a)–(d) *Andromeda polifolia*: (a) leaves and twig; (b) remains *in situ*; (c) leaf epidermis; (d) seed. (e)–(g) *Vaccinium oxycoccus*: (e) stems with leaves; (f) remains *in situ*; (g) leaf epidermis. (h) Ericales, rootlets. (i) *Drosera intermedia*, seed; (j) *Drosera rotundifolia* or *D. anglica*, seed. (k)–(m) *Eriophorum vaginatum*: (k) stem and leaf remains; (l) part of stem with some *in situ* spindles and separate spindles; (m) epidermis.

Figure 3 (a) *Eriophorum angustifolium*, lower parts of stems; (b) *Eriophorum* spp., seeds. (c)–(f) *Rhynchospora alba*: (c) leaf; (d) detail of leaf with sheath; (e) leaf epidermis; (f) seeds; (g) *Carex rostrata*, perigynium and achenes. (h)–(j) *Carex* cf. *limosa*: (h) rhizome fragment; (i) and (j) root. (k) *Carex* spp., root. (l)–(n) *Scirpus cespitosus*: (l) remains *in situ*; (m) leaf; (n) leaf epidermis. (o) *Cladium mariscus*, stem base. (p) *Typha* spp., seed.

angustifolium offers it a degree of fire resistance (Phillips, 1954). Boatman and Tomlinson (1977) and Rodwell (1991) confirmed its position at the edges of pools (where it can dominate), in permanent shallow pools, and in dried-up hollow bottoms, as it can tolerate a range of moisture conditions. Van der Molen (1988) noted its occurrence in hollow microforms, with a mean height above the water table of 8–10 cm.

Rhynchospora alba

R. alba (Figure 3(c)–3(f)) is a good indicator of high-mire water tables as it occurs in low lawns and at pool margins (Godwin and Conway, 1939). Its mean height above the water table appears to be 12–14 cm (van der Molen, 1988). Hammond et al. (1990) and Økland (1990) report slightly lower values of 8 and 5–7 cm, respectively, to the water table, with the range extending from 0 to 10 cm. Rodwell (1991) describes the position of *R. alba* as being confined between low lawns and the shallower water around pool margins, from where it may, sometimes, extend across smaller mire pools.

Carex spp. (*Carex rostrata* and *Carex limosa*)

These Cyperaceae (Figure 3(g)–3(k)) occur in mesotrophic and poor fens, although *Carex limosa* can also be found in ombrotrophic bog pool communities. *Carex* spp. macrofossils have been used to identify the fen/bog transition in UK peatlands (Hughes and Barber, 2004).

Scirpus cespitosus (*Trichophorum cespitosum*)

Scirpus cespitosus (Figure 3(l)–3(n)) is typically found on drier areas of raised and blanket peat bogs (Rodwell et al., 1991). On the better drained Rand (sloping margins) of raised peat bogs it is frequently recorded (Godwin, 1975).

Cladium mariscus

Cladium mariscus (Figure 3(o)) grows in calcium rich and nutrient poor, shallow water bodies, for example, in fens and swamps. Macrofossils of this sedge have been recorded with *Phragmites australis* to indicate a reedswamp phase (Hughes and Barber, 2003).

Typha angustifolia and *Typha latifolia*

Typha spp. (Figure 3(p)) produce enormous quantities of wind-dispersed seeds and the presence of low numbers of seeds does not necessarily indicate its local presence. In combination with the pollen record its local presence in terrestrialization phases becomes clear (rooting in nutrient-rich substrates).

Scheuchzeria palustris

Scheuchzeria palustris (Figure 4(a)–4(f)) grows in permanent standing water or in places where local water tables are high (Moore, 1955; Tallis and Birks, 1965). Its occurrence in very wet and slightly minerotrophic peatland microforms has also been confirmed by Økland (1990) using ordination

techniques. Casparie (1972) also mentions its presence can indicate slight minerotrophy in subfossil peat samples. Thick layers of *Scheuchzeria palustris* 'precursor peat' can precede the deposition of later *Sphagnum*-rich levels in peat bog deposits.

Menyanthes trifoliata

Menyanthes trifoliata (Figure 4(g)–4(i)) is an aquatic perennial herb that occurs in a range of aquatic mesotrophic/eutrophic/oligotrophic peatland communities, where water levels are at or above the ground surface (Godwin, 1975; Hewett, 1964).

Potentilla palustris

Potentilla palustris (Figure 4(j)) grows in fens, wet meadows, and lake margins.

Myrica gale

Myrica gale (Figure 4(k)) is a deciduous shrub that chiefly grows on both acidic fens and bogs (marginal slopes of raised bogs) over a pH range of 3.8–6.1 (Skene et al., 2000).

Juncus

Various *Juncus* spp. (Figure 4(l)–4(n)) occur in wet meadows, along shores and in gradient and pioneer situations. The plants produce enormous amounts of seeds. Körber-Grohne (1964) made a useful illustrated key for *Juncus* seeds in northwest-European deposits.

Molinia caerulea

Molinia caerulea (Figure 5(a) and 5(b)) is a perennial grass that has a bimodal pH distribution (pH < 4 and pH > 7, Grime et al., 1988) and can grow in both bog or fen sites where total waterlogging is absent (Godwin, 1975). It is most abundant in sites where there is ground-water movement, good soil aeration during the growing season, and an enriched nutrient supply. It is tolerant of burning (Taylor et al., 2001).

Phragmites australis

Phragmites australis (Figure 5(c)–5(f)) grows in fens, shallow lakes, salt marshes, and flushed areas of bog edges, in low-lying areas intermittently or permanently flooded with shallow or still water (pH range for well-grown stands of 5.5–7.5, but can occur where pH is as low as 3.6, Haslam, 1972). The roots can extend to 100 cm in depth.

Tree Macrofossils – *Alnus glutinosa*, *Betula* spp., *Pinus sylvestris*, *Populus tremula*

Alnus, *Betula*, and *Pinus* (Figures 5(g)–5(n) and 6(a)–6(d)) grow in 'bog woodland,' and base-rich mires ('fen carr'). Buds, bud scales, catkin scales, fruits, leaf fragments, and needles of these trees have been recorded in peat profiles (Hannon et al., 2000; Hughes and Barber, 2004), particularly in deposits spanning the fen/bog transition (Hughes et al., 2000). Remains of *Populus tremula* (Figure 5(o) and 5(p)) often occur in early

Figure 4 (a)–(f) *Scheuchzeria palustris*: (a) rhizomes and leaf remains; (b) rhizome epidermis; (c) leaf epidermis with stoma; (d) and (e) hydathode; (f) seeds. (i)–(n) *Betula* spp.: (i) seed; (j) *Betula nana*, female catkin scale; (k) tree birch, female catkin scale; (l) detail of leaf; (m) *B. nana*, leaf; (n) *Betula* spp., periderm. (o) and (p) *Populus tremula*: (o) catkin bracts; (p) bud scale.

Figure 6 (a)–(d) *Pinus sylvestris*: (a) needles; (b) needle epidermis with stomata; (c) periderm; (d) mycorrhizal roots. (e) and (f) *Potamogeton*, leaf fragment. (g)–(i) *Ceratophyllum*: (g) leaf with spines *in situ*; (h) spine; (i) seed. (j)–(n) *Nymphaeaceae*: (j) leaf epidermis; (k) leaf fragment with trichosclereids; (l) trichosclereid; (m) *Nymphaea*, seed; (n) *Nymphaea*, seed epidermis.

Holocene deposits, for example, in small depressions, indicating stands of *Populus* on drier soils (van Geel et al., 1981).

Potamogeton

Seeds of *Potamogeton* can be identified with the study by Aalto (1970), but also leaf remains with their characteristic venation (parallel, with connections (Figure 6(e) and 6(f))) can be common in lake deposits.

Ceratophyllum

Ceratophyllum spp. (Figure 6(g)–6(i)) are underwater rootless perennial plants which occur in nutrient-rich water. Pollen of *Ceratophyllum* does not preserve, and seeds are quite rare. However, the characteristic leaf spines are common in pollen slides and leaf fragments with *in situ* leaf spines can be found in macrofossil samples of lake deposits.

Nymphaeaceae

Asterosclereids and the suberized basal cells of Nymphaeaceae mucilaginous hairs (Figure 6(j)–6(n)) are frequently found in pollen slides from lake and pool deposits and indicate their local presence (Pals et al., 1980).

Trapa natans

Water chestnut (*Trapa natans*; Figure 7(a)) is an annual aquatic plant that grows at a depth of 1–2 m in lakes and former river channels with a muddy bottom and fairly warm water. The fruit has a very hard, rough shell with four sharp spines (Figure 7(a) shows a spine). Fossil fruits have been identified by Korhola and Tikkanen (1997), most abundantly in shallow, eutrophic water, prior to final infilling of lake basins (Schofield and Bunting, 2005).

Equisetum

The above-ground remains of *Equisetum fluvatile* (Figure 7(b)–7(f)) in peat deposits are black, while rhizomes and roots are dark-brown. Rhizome epidermis cells are long and show a very regular pattern with zip-connections between the cells. Dark parts with lighter spots in the epidermis are a characteristic feature. The outer cell layer of the roots show long and short cells, with simple cell structure (no zip-connections).

Thelypteris palustris

Thelypteris palustris (Figure 7(g)–7(k)) can be an important peat former in Holocene deposits formed under eutrophic conditions. Often leaf fragments, curved ends of leaf axes, roots, and tracheids are preserved (Grosse-Brauckmann, 1972a). Fern sporangia are common in *Thelypteris* peat.

Characeae

Oospores of Characeae (Figure 7(l)) are often numerous in lake deposits, especially when these deposits were formed in pioneer conditions (inputs of minerogenic material). A key for

central European charophyte oospores and a discussion of their ecology is available (Haas, 1994).

Gloeotrichia

Globular colonies consisting of hyaline sheaths of *Gloeotrichia*-type (Figure 7(m) and 7(n)) regularly occur in shallow freshwater deposits (van Geel et al., 1989, 1994, 1996). Increases of Cyanobacteria can indicate eutrophication (increased phosphorus loading which may cause nitrogen-limited growth conditions). In such conditions Cyanobacteria capable of nitrogen fixation can thrive. *Gloeotrichia*-type was also observed in nutrient-poor pioneer conditions at the start of the Late-Glacial period (van Geel et al., 1989).

Sphagnum austinii (*Sphagnum imbricatum* spp. *austinii*)

This *Sphagnum* spp. (Figure 8(a) and 8(b)) is particularly striking since its hyaline cells possess numerous transverse lamellae, which appear to be comb-like (Smith, 2004). The ecology of modern examples of this species indicates that it is a bryophyte capable of growing under relatively xeric conditions. Like other members of section *Sphagnum*, it has both inrolled cucullate (hooded at the apex) leaves, and grows in a compact form with a very close and imbricate arrangement of the branch leaves. This serves to reduce the surface area for evaporation (Flatberg, 1986). Green (1968) experimentally demonstrated its ability to retain water, while Flatberg (1986) confirmed its presence in (high) hummocks. Detailed paleoecological macrofossil analysis undertaken by van der Molen and Hoekstra (1988) highlight the ability of this bryophyte to grow under dry mire surface conditions in the past.

Sphagnum imbricatum spp. *austinii* does, however, have morphologically distinct ecads or ecophenes, which allow it to grow in both hummocks and (low) lawns. The lawn ecad has a lax growth form, which has been experimentally induced by Green (1968). The ability of *Sphagnum imbricatum* to grow under wetter mire surface conditions has been demonstrated in the fossil record by Casparie (1972), van Geel (1978), and Barber (1981). The disappearance of *Sphagnum imbricatum* from the stratigraphy of British and Irish peatlands has been noted by many paleoecologists (see the review in Mauquoy and Barber, 1999). The reasons for the disappearance of *Sphagnum imbricatum* in northwest European peat deposits are still not clear. It may result from a possible combination of climatic changes and eutrophication (deposition of nutrients bound to soil dust following human disturbance).

Sphagnum magellanicum

Subfossil leaves of *Sphagnum magellanicum* (Figure 8(c)–8(f)) are readily recognized by their photosynthetic cells, which are oval and largely enclosed by hyaline cells (Smith, 2004). Andrus et al. (1983) recorded *Sphagnum magellanicum* in lawns and low hummocks (25.8 ± 9.5 cm above the spring water table). Hammond (1990) found that 90% of the occurrences of *Sphagnum magellanicum* occurred at a water table depth of 24 cm. Økland (1990), however, suggests it has a broad habitat niche. The species became dominant in many raised bogs during the last millennium.

Figure 7 (a) *Trapa natans*, barbed appendage of seed. (b)–(f) *Equisetum fluviatile*: (b) rhizome epidermis; (c) leaf; (d) and (e) stem diaphragm; (f) root. (g)–(k) *Thelypteris palustris*: (g) leaf fragment; (h) young fossilized stems with folded leaves; (i) fern sporangium (*Thelypteris*-type); (j) tracheids; (k) root. (l) Characeae, oospore. (m) and (n) *Gloeotrichia*-type, colony. (o) *Sphagnum* peat.

Figure 8 (a) and (b) *Sphagnum austinii* (*S. imbricatum* spp. *austinii*): (a) leaf; (b) transverse lamellae in hyaline cells. (c)–(f) *Sphagnum magellanicum*: (c) leaf; (d), (e), and (f) high, middle, and low focus. (g) and (h) *Sphagnum papillosum*: (h) papillae on cell walls. (i)–(k) *Sphagnum palustre*: (i) leaf; (j) and (k) dorsal high and low focus. (l)–(n) *Sphagnum* sect. *Cuspidata*: (l) leaf, (m) and (n) ventral high and low focus. (o)–(q) *Sphagnum* cf. *tenellum*: (o) leaf; (p) and (q) ventral high and low focus. (r)–(t): *Sphagnum* sect. *Acutifolia*: (r) leaf; (s) and (t) dorsal high and low focus.

Sphagnum papillosum

The internal commissural walls of *Sphagnum papillosum* (Figure 8(g) and 8(h)) are rough since they possess projecting papillae (Smith, 2004). This distinctive feature of the hyaline cells makes identification of *Sphagnum papillosum* straightforward. Boatman (1983) found it predominantly in low lawns and pools in the Silver Flowe complex of bogs in southwest Scotland. Its 10–12 cm mean height above the water table also suggests an optimal low lawn position (Janssens, 1992; van der Molen et al., 1994). Conversely, Hammond et al. (1990) found that 90% of the occurrences of the species were at relatively high positions on lawns (23 cm), just below the optimum value for *Sphagnum magellanicum* (24 cm). Økland (1990) made similar findings since it was recorded largely in lawn microforms, and only rarely in hummocks as single shoots. This species appears to have a wide ecotop breadth, like *Sphagnum magellanicum*, although its optimum position would appear to be centered on low lawn positions.

Sphagnum palustre

The branch leaves of *Sphagnum palustre* (Figure 8(i)–8(k)) are ovate or broadly ovate and the apex has a hood-shaped tip. The photosynthetic cells are variable in shape and can be either triangular and fully exposed on the ventral surface, barrel-shaped and broadly exposed ventrally, or lens-shaped with negligible ventral exposure (Smith, 2004). This species can be found in mesotrophic marshes, stream sides, and in wet woodlands. Macrofossils of *Sphagnum palustre* in poor fen peat deposits have been identified by Hughes et al. (2000).

Sphagnum Section *Cuspidata*

Species within section *Cuspidata* (Figure 8(l)–8(n)) can be identified by their ovate-to-lanceolate shape, narrow hyaline cells, and their triangular-to-trapezoidal-shaped photosynthetic cells broadly exposed on the dorsal surface. The leaves of *Sphagnum cuspidatum* are particularly distinctive, as they may extend to 3.5 mm in length. Section *Cuspidata* leaves are predominantly found in pool and low lawn ecotopes, and are therefore a good indicator of raised mire water levels.

Sphagnum Section *Acutifolia*

Leaves from *Sphagnum* section *Acutifolia* (Figures 8(r)–8(t) and 9(a)–9(d)) are readily recognized by their ovate-to-narrow ovate branch leaves (Smith, 2004), which are small in *Sphagnum fuscum* (1.1–1.3 mm in length) and *Sphagnum capillifolium* (0.8–1.4 mm) and rather bigger in *Sphagnum subnitens* (1.2–2.7 mm) and *Sphagnum molle* (1.4–2.3 mm). All of the species within the section possess triangular photosynthetic cells broadly exposed on the ventral surface and possess similarly sized dorsal pores (up to 30 µm). The overlapping size ranges of the branch leaves, makes positive identification to species level difficult (unless stem leaves are present, as these are very valuable in aiding identification, see Johansson, 1995).

The difficulty of consistently and accurately identifying leaves to species level also poses problems in determining the degree of mire surface wetness. This is not such a problem for

either *Sphagnum fuscum* and *Sphagnum capillifolium* var. *rubellum* leaves, since they occupy hummocks; Andrus et al. (1983) found the two species growing at mean heights of 30.9 ± 10.6 and 24.8 ± 9.4 cm above the spring water table, respectively. Rydin and McDonald (1985) similarly found the two species at respective heights of 35 and 25 cm above the water table, while Janssens (1992) derived an optimum height of 27.5 cm above the mean water table for *Sphagnum fuscum*.

Sphagnum molle and *Sphagnum subnitens* are, however, lawn species (Smith, 2004), which reduces the accuracy of any paleoecological reconstruction made using branch leaves identified to *Sphagnum* section *Acutifolia* alone.

Sphagnum Section *Subsecunda*

Branch leaves in *Sphagnum* section *Subsecunda* (Figure 9(e) and 9(f)) are typically 0.7–2.5 mm long and 0.4–1.5 mm wide. Numerous small dorsal/ventral pores are present along the commissures (the junction between the hyaline and the green cells), with up to 40 and 20 per cell, respectively. Species in this section can be found in depressions (often submerged), in base-rich flushes, fens, woods, and moors.

Aulacomnium palustre

The leaf cells of *Aulacomnium palustre* (Figure 9(i) and 9(j)) have rounded lumens. This moss grows at relatively high positions above the water table, for example, Andrus et al. (1983) recorded it at positions 30.0–31.4 cm above the spring water table, in small patches on hummock sides. Økland (1990) similarly confirms the presence of this species within upper hummocks and, additionally, as ‘single shoots’ among *Sphagnum* species. Nicholson and Gignac (1995) found it growing at a greater range of heights above the water table (10–40 cm).

Polytrichum commune and *Polytrichum juniperinum*/ *alpestre*-Type

Polytrichum commune (Figure 10(a)–10(c)) grows under a wide range of acidic habitats, including heaths, woods, wet moorlands, bogs, lake margins, pools, and stream sides in damp-to-wet microhabitats. It is commonly associated with a range of *Sphagnum* spp., especially *Sphagnum palustre* and *Sphagnum recurvum*. *Polytrichum juniperinum* (Figure 9(k)–9(o)) grows on well-drained acidic soils on heaths and moors (Dickson, 1973; Smith, 2004). *Polytrichum alpestre* similarly displays a preference for drier microforms and has been interpreted as a hummock-level moss (Hughes et al., 2000), since it forms dense tussocks on ombrotrophic bogs (Dickson, 1973).

Paludella squarrosa

Paludella squarrosa (Figure 10(d)–10(f)) is a moss that occurs in fens and subfossil leaves identified in a peat profile collected from the east-European Russian Arctic have been used to show a wet and mesotrophic phase in the local peatland succession (Välranta et al., 2003).

Figure 9 (a)–(d) *Sphagnum fuscum* (recent): (a) and (b) leaf and stem leaf; (c) and (d) ventral high and low focus. (e) and (f) *Sphagnum* sect. *Subsecunda*. Figure 10 (a)–(c) *Polytrichum commune*: (a) leaf; (b) detail of leaf with lamellae; (c) leaf base. (d)–(f) *Paludella squarrosa*; (g) and (h) *Calliergon giganteum*; (i) and (j) *Drepanocladus* cf. *aduncus*.

Calliergon giganteum

Calliergon giganteum (Figure 10(g) and 10(h)) is a moss that primarily occurs in rich fens. Subfossil leaves of *Calliergon giganteum* were identified by van Geel et al. (1986) and used to indicate stagnant, eutrophic, and base-rich aquatic environments in an Eemian lake deposit.

Drepanocladus spp. (Figure 10(i) and 10(j))

Drepanocladus aduncus is an aquatic moss which occurs in moderate-rich fens, small lakes, ponds, or streams. *Drepanocladus fluitans* is found in pools in blanket bogs, sometimes with *Sphagnum cuspidatum*. Watson (1968) describes it as a species that can tolerate both aquatic and terrestrial habitats, since it is found both in deep pools and in sites which are only periodically wet. Dickson (1973), however, places *Drepanocladus fluitans* as a species primarily found in base-poor pools. Ohlson and Malmer (1990) corroborate this, as they recorded *Drepanocladus fluitans* with *R. alba* growing in mud-bottom communities.

Fungi

Fungal fruit bodies (~125–500 µm in diameter) are regularly recorded in raised bog macrofossil samples (van Geel, 1978). The dark-brown fruit bodies are often still filled with ascospores. *Meliola ellisii* (Figure 11(b)) is an obligate parasite on *Calluna vulgaris*. The currently unidentified Type 18 (Figure 11(a)) occurs on roots of *Eriophorum vaginatum*. Mycelium with chlamydospores of *Glomus* cf. *fasciculatum* (Figure 11(c)) can be common in various types of (nonoligotrophic) peat deposits. It grows as a vesicular-arbuscular endomycorrhizal fungus on a variety of host plants. In lake sediments the presence of *Glomus* indicates soil erosion in the catchment of the lake (Anderson et al., 1984).

Freshwater Sponges

Spicules and gemmules of freshwater sponges (Figure 11(e) and 11(f)) are of regular occurrence in macrofossil samples, especially in shallow water deposits at transitions from open water in the first stage of terrestrialization (Harrison, 1988; van Geel et al., 1989).

Chironomidae and Trichoptera

The chitinous larval remains of chironomids (Figure 11(g) and 11(h)) are very useful in paleoenvironmental studies of lake sediments (Walker, 2001). For the use of caddis fly larvae remains we refer to Elias (2001).

Acari (Oribatid Mites)

The majority of oribatid mites (Figure 11(i)) have a sclerotized, chitin-rich cuticle. They are soil dwellers, common in peat deposits, but normally no records are made and for identifications specialist literature and the help of an acarologist is essential (Schelvis and van Geel, 1989). For an overview of the potential use of mites in paleoecology see Solhøy (2001).

Piscicola geometra

Piscicola geometra (Figure 11(j)) is an external parasite of freshwater fish. They lay their eggs in cocoons on the pond bottom, plants, stones, etc. Cocoons can be common in lake deposits (Pals et al., 1980).

Bryozoa

Bryozoa (Figure 11(k)–11(m)) are small, sessile, colonial, and filter-feeding animals. There are more than 65 freshwater species worldwide. Bryozoa of the class Phylactolaemata produce asexual buds called statoblasts. These consist of two chitinous valves with regenerative cells within, and function as reproductive, survival, and dispersal agents. Statoblasts can be identified and provide information on past aquatic environments (Francis, 2001).

Foraminiferae

In peat deposits and lake sediments, the presence of linings of foraminiferae (Figure 11(n)) indicate temporary inundation with salt or brackish water.

Ostracods

Ostracods (Figure 11(o)) are bivalved aquatic crustaceans with shells, common in nonmarine waters with neutral-to-alkaline pH. Ostracods are sensitive to a range of ecological factors (Holmes, 2001).

Callidina angusticollis

The loricas of *Callidina angusticollis* (Figure 11(p)) are of regular occurrence in Holocene raised bog deposits, but to date no specific ecological information can be derived from the occurrence of this representative of the Rotifera (van Geel, 1978).

Diaptomus cf. *castor*

According to Bennike (1998) the egg sacs of *Diaptomus* cf. *castor* (Figure 11(q)) might indicate low arctic or subarctic climates, but that idea must be incorrect, as van Dam et al. (1988) recorded them from late Holocene moorland pool deposits in The Netherlands.

Conclusions

High-quality macrofossil datasets from peat deposits can be used to reconstruct the former degree of mire surface wetness, successional processes of the local peat-forming vegetation, trophic/pH status, and assess the effect of human disturbance (e.g., burning, drainage, and rapid forest expansion; Pellerin and Lavoie, 2003). A thorough knowledge of the present-day ecology of the plants growing in bogs and fens is essential in order to make accurate paleoenvironmental reconstructions, and provides the basis for evaluating the subfossil presence of these plants (the individualistic approach, Birks and Birks, 2003). We have, therefore, compiled and reviewed a selection

Figure 11 (a) Fungal fruit body (Type 18; not identified) in roots of cf. *Eriophorum vaginatum*. (b) *Meliola ellisii*, fruit body with ascospores. (c) *Glomus*, mycelium with chlamydospores. of literature on the actuo- and paleoecology of peat-forming plants to guide the interpretation of subfossil peat sequences. Identifications of mire and peat macrofossils can often be made to species level, and is the key advantage of the technique compared to pollen analysis, since grains and spores are usually only identifiable to family or genus level and may come from a variety of habitats outside the peat-forming wetland. Our illustrations of a range of mire and peat macrofossils may help to identify remains of peat-forming plants, but we stress that type material (preferably fossil) is the best way to confirm correct identifications.

Paleolimnological Applications

M-J Gaillard, Linnaeus University, Kalmar, Sweden

H H Birks, University of Bergen, Bergen, Norway

© 2013 Elsevier B.V. All rights reserved.

This article is reproduced from the previous edition, volume 3, pp. 2337–2356, © 2007, Elsevier B.V.

Plant macroremains are usually well preserved in anaerobic lake sediments. The macrofossil assemblages are usually dominated by aquatic and shore plants and the plants in the catchment. The most common subfossil plant remains are seeds, fruits, and leaves, but other characteristic parts may also be identified and used in reconstructions. For a more comprehensive overview of plant macroremains in lake sediments, see Birks (1980, 2001).

This article focuses on the contribution of plant macrofossil analysis to paleolimnology. We discuss the past development of the macrophyte flora (submerged, floating-leaved, and emergent lakeshore plants) and of lake ecosystems in general, including water characteristics (pH, nutrients, and temperatures), and eutrophication; we also describe the use of plant macrofossils in reconstructions of past lake level changes.

The Role of Macrophytes in a Lake Ecosystem and Factors Affecting Their Distribution in a Lake

Macrophytes are an important component of lake ecosystems and their processes (Jeppesen et al., 1998). They play a primary role in the formation and stabilization of lake sediments, such as gyttja and marl. They recycle nutrients from the sediment and the lake water, which influences the trophic status of water bodies. They provide food and habitats for many other lake organisms (algae and animals). Thus, the analysis of plant remains in lake sediments provides information on these aspects of the lake ecosystem through time.

The principal factors affecting the structure and composition of aquatic vegetation within a lake are water depth (and related water transparency; Hannon and Gaillard, 1997), water chemistry and nutrient-status (pH, alkalinity, base cations, nitrogen, and phosphorus; Jackson and Charles, 1987; Scheffer et al., 1993), and temperature (Iversen, 1954; Kolstrup, 1980) (Table 1 and Figures 1 and 2).

Lakes can be classified into four main ecological types (Lang, 1994; Hannon and Gaillard, 1997), which have characteristic littoral vegetation zones (Figure 3):

1. Eutrophic lakes (high phosphorus and nitrate content, pH 7 or above, calcareous or not) with well-developed belts of lakeshore vegetation (supralittoral and eulittoral zones) and of submerged and floating-leaved species (sublittoral zone), with each belt being related to a range of water depths.
2. Oligotrophic lakes (low phosphorus content, calcareous rich with pH 7 or above, or calcareous poor with pH 6 or 7) with less dense and diverse littoral vegetation than eutrophic lakes and few distinct vegetation zones.
3. Mesotrophic lakes are intermediate between eutrophic and oligotrophic lakes.

4. Dystrophic lakes (very low phosphorus, noncalcareous, pH 6 or lower) often lack macrophytes. They may have floating marginal mats of *Sphagnum* and *Carex* spp.

Newly formed lakes are rapidly colonized by macrophytes, often in a few decades. A hydrosere (aquatic succession) then proceeds, controlled by internal factors in the lake. The hydrosere may be disrupted or diverted by external factors, such as local or regional human-induced or climatic factors, that result in changes in lake nutrient status and/or water chemistry (Figure 4). Natural hydroseres progress over centuries and the paleolimnological macrofossil record is the only way of documenting long-term hydrosere processes in lake ecosystems (Birks, 2000) and is necessary even if historical records are available (Davidson et al., 2005). Hence, paleolimnology relates the ecological history of lakes to their present ecosystems (Smol, 2002).

Examples of Plant Macrofossil Analysis in Paleolimnological Studies

Late Glacial Paleolimnology

The contribution of plant macrofossil analysis to multidisciplinary studies of Late Glacial lake sediments is discussed elsewhere in this encyclopedia. Iversen (1954) emphasized the indicator value of aquatics as proxies of climate change because they behave as pioneer species, not requiring mature soil to grow. Because they find ideal conditions in a lake relatively soon after its formation, Iversen argued that aquatic plants should react more rapidly to climate warming than terrestrial plants. Aquatics have been used as Late Glacial temperature indicators in The Netherlands (Kolstrup, 1980) and in southwest Switzerland (Gaillard, 1984a, 1985; Table 1). In Switzerland, aquatics were already present during the oldest Late Glacial period from ca. 15 000 uncal ¹⁴C BP (Figure 5). Many of the species present during that period (*Myriophyllum spicatum*, *Potamogeton gramineus*, *P. praelongus*, *P. filiformis*, and *Ranunculus* sect. *Batrachium*) became more abundant from the time of expansion of the dwarf birch (from ca. 14 000 uncal ¹⁴C BP). *Typha latifolia*, *Nymphaea alba*, *Utricularia* spp. *Potamogeton lucens*, *P. perfoliatus*, *P. pusillus*, *P. pectinatus*, *Alisma plantago-aquatica*, *Myriophyllum verticillatum*, and *Hippuris* first appeared with the development of tree birch from 12 700 uncal ¹⁴C BP. On the basis of that data and the indicator value of aquatics (Table 1), Gaillard (1985) suggested that July temperatures had already exceeded 10 °C at the end of the Oldest Dryas at approximately 14 000 uncal ¹⁴C BP. A further increase to more than 13 °C took place ca. 12 700 uncal ¹⁴C BP.

In contrast, in Norway at Kråkenes, *Ranunculus* sect. *Batrachium* and *Nitella* were the earliest pioneers after deglaciation

Table 1 Minimum and optimum mean July temperatures of some lake macrophytes^a

Macrophyte taxa	Minimum mean July temperature (°C)	Optimum mean July temperature (°C)
<i>Alisma plantago aquatica</i>	>10	>13
<i>Ceratophyllum demersum</i>	13	15
<i>Cladium mariscus</i>	>15	17
<i>Hippuris vulgaris</i>	>10	>13

<i>Myriophyllum alterniflorum</i>	10	>10
<i>Myriophyllum spicatum</i>	10	>10
<i>Myriophyllum verticillatum</i>	>10	>13
<i>Nuphar lutea</i>	>15	17
<i>Nymphaea alba</i>	>10	>13
<i>Potamogeton filiformis</i>	8	
<i>Potamogeton gramineus</i>	8	
<i>Potamogeton lucens</i>	>10	>13
<i>Potamogeton pectinatus</i>	>10	>13
<i>Potamogeton perfoliatus</i>	>10	>13
<i>Potamogeton praelongus</i>	8	
<i>Potamogeton pusillus</i>	>10	>13
<i>Schoenoplectus lacustris</i>	>10	>13
<i>Typha latifolia</i>	12–13	15
<i>Typha angustifolia</i>	>14	

^aAccording to Kolstrup (1980) and Gaillard (1984a).

ca. 12 300 uncal ¹⁴C BP (Figure 6; Birks, 2000). The vegetational succession was very slow between 12 000 and 10 900 uncal ¹⁴C BP, inhibited by cool conditions similar to those above treeline in Norway today. The rapid cooling at the start of the Younger Dryas stadial resulted in almost complete extermination of limnic plants and animals.

The Late Glacial and Holocene (18 000–6000 cal BP) plant macrofossil record at Lake Zeribar, Zagros Mountains, Iran, documents increased salinity (occurrence of *Ruppia maritima*) during cold periods. The presence of *Ceratophyllum demersum* during the Bølling/Allerød period was ascribed to rising temperatures. The macrofossil record from Zeribar also provides information on lake level fluctuations.

Holocene Paleolimnology

A feature of the early Holocene macrofossil flora is the abundance and rapid successions of macrophytes. In central Europe (Gaillard, 1984a; Ammann and Tobolski, 1983), Late Glacial taxa such as *Ranunculus* sect. *Batrachium*, *Potamogeton* spp. (e.g. *P. gramineus*, *P. pusillus*, *P. lucens*, and *P. filiformis*), and *Myriophyllum spicatum*, are often replaced by *Nymphaea alba*, *Nuphar lutea*, *Ceratophyllum demersum*, and *Trapa natans* and emergents such as *Comarum palustre*, *Cladium mariscus*, *Menyanthes trifoliata*, and *Carex* spp. (Figure 5).

In southwestern Switzerland (Gaillard, 1984a, 1985), the early Holocene is characterized by a renewed development of *Potamogeton* spp., *M. spicatum*, and *Nymphaea alba*, and by the first occurrence of *Ceratophyllum demersum*. The occurrence of the thermophilous lakeshore species *Cladium mariscus* suggests

that minimum July temperatures had reached ca. 17 °C in the earliest Holocene (Table 1).

Kråkenes, western Norway (Birks, 2000) provides a contrast. The biotic response to the rapid warming of the early Holocene (10 000 uncal ¹⁴C BP; 11 530 cal BP) was immediate. The pioneers *Ranunculus* sect. *Batrachium* and *Nitella* expanded within one to three decades, closely followed by other elodeids. From 11 430 to 10 720 cal BP, a remarkable isoetid succession took place, with phases dominated by *Limosella aquatica*, *Subularia aquatica*, *Elatine hydropiper*, and *Isoetes echinospora*. Approximately 800 years into the Holocene, most of the macrophytes declined, which was probably related to nutrient depletion in the base-poor catchment (Birks, 2000). Approximately 550 years later, *I. lacustris* and *Nymphaea* colonized, and a stable flora developed (Figure 6).

At Lake Zeribar, Iran, the replacement of *Najas marina* by *Najas minor* approximately 11 000 cal yr BP was interpreted in terms of increasing temperatures and decline in salinity (Wasylikowa, 2005).

During the middle and late Holocene, changes in the macrophyte flora were generally due to processes such as infilling, eutrophication, or acidification, or to lake level fluctuations. Although it was prominent in the early Holocene, *Cladium mariscus* often declined from 7000 to 6000 cal yr BP (Gaillard, 1984a). This strongly calciphilous species was affected by the gradual leaching of carbonates and the progressive acidification of soils. In Scandinavia, *Cladium* is still common on the islands of Öland and Gotland, both characterized by calcareous bedrocks.

Väliiranta (2005) investigated changes in aquatic and terrestrial environments of northeastern European Russia and Finnish Lapland using plant macrofossil analysis, pollen, and other proxy data. Similar long-term patterns in early Holocene expansion of aquatics, a subsequent maximum in aquatic species richness, and a decline or disappearance of aquatics after the middle Holocene were recorded regardless of the lakes' locations in different vegetation and climate zones (Figure 7; Kultti et al., 2003, 2004). Väliiranta suggests that the early Holocene warming and sufficient nutrient status enabled the immigration and establishment of aquatic plant communities. Subsequently, as summer temperatures gradually declined through the Holocene, the length of the open-water season (i.e. temperature-related parameters) probably controlled the absence or presence of limnophytes.

Coastal Environments

The history of coastal environments may provide information on past changes in sea level. There are many examples of such studies in the literature; however, seldom are they supported by plant macrofossil records.

In the context of an archaeological study of the Mesolithic settlements (ca. 7000–5500 uncal yr BP) at Skateholm, Skåne, south coast of Sweden, the sediments from an ancient lagoon were studied for pollen, plant macrofossils, insects, and diatoms (Gaillard and Lemdahl, 1988). The record of plant remains was remarkably species rich (Figures 8 and 9). The local vegetation around the settlements and the trophic state, the salinity, and the water level of the lagoon were reconstructed. Between the settlements and the sea, a wetland landscape was characterized

Figure 1 Potential depth ranges of emergent, floating-leaved, and submerged lakeshore and aquatic taxa. After Hannon GE and Gaillard M-J (1997) The plant-macrofossil record of past lake-level changes. *Journal of Paleolimnology* 18:15–28.

by zones of swampy alder forest; reed swamp (*Phragmites*); and open, shallow brackish, mesotrophic to eutrophic water (with *Ruppia maritima*, *Zannichellia palustris*, *Najas marina*, and *Chara*). The lagoon was particularly shallow and sheltered between 6900 and 6200 BP. The sea progressively invaded the basin (*Littorina* transgression), which resulted in the retreat of the marginal alder woods. Between 5800 and 4000 BP, the lagoon was more open to the sea, becoming a shallow bay.

Eutrophication

Very few modern lake ecosystems are unaffected by human activity. A common source of ecosystem disruption is eutrophication through the addition of nutrients (nitrates and phosphates). They may derive from agricultural runoff or from

sewage. In several cases, the effects have been highly undesirable. Macrophyte productivity increases. Boat propellers and fishing lines become entangled. The decay of the increased bioproduction results in anaerobic conditions, which can lead to fish kills and the production of unpleasant smells from sulfides in the sediments. Dense macrophyte growth shades out smaller species and alters the habitats and balance of invertebrates and fish. If phytoplankton and epiphytic algal growth increases, macrophytes may be shaded out and a complete reorganization occurs (alternative stable state; Scheffer et al., 1993) in which, during summer, the water is full of cyanobacteria (green slime) and macrophytes are absent.

How are the presence and abundance of macrophytes during cultural eutrophication represented by macrofossils? Davidson et al. (2005) tested the macrofossil record at Groby

Figure 2 Water pH ranges of aquatic macrophyte taxa from 31 unproductive lakes in the Adirondack Mountains (New York). Non-European species are indicated with an asterisk. After Jackson ST and Charles DF (1987) Aquatic macrophytes in Adirondack (New York) lakes: Patterns of species composition in relation to environment. *Canadian Journal of Botany* 66: 1449–1460; simplified by Hannon GE and Gaillard M-J (1997) The plant-macrofossil record of past lake-level changes. *Journal of Paleolimnology* 18: 15–28.

Pool, central England, against an exceptional floristic record spanning 250 years. Approximately 40% of the macrophytes were recorded as macrofossils, highlighting their irregular production and poor dispersal. However, several taxa were found as macrofossils that were not recorded in the lake, showing that visual recording of macrophytes is also fraught with difficulties. In general, the sediments recorded more detailed changes than the rather irregular recording visits, but both records showed similar changes over time, suggesting that, even if it is incomplete, the macrofossil record provides good insight into macrophyte community dynamics and successions.

A 7000-year-long macrofossil record from Gundsømagle Sø, a lake in eastern Denmark currently dominated by *Nymphaea alba* (Rasmussen and Anderson, 2005), shows limnological responses to changes in external factors such as climate, land use, and changing chemical composition of the inflow water and also to internal (autogenic) factors such as competition and

sediment accumulation (Figure 10). The macrofossils record sparse macrophyte vegetation characteristic of clear-water alkaline mesotrophic lakes before ca. 3200 BP, probably limited by low light in the relatively deep (>5 m) water at the coring site. Subsequent erosion from extensive Bronze and Iron Age clearances and agriculture increased the sediment load to the lake. Submerged and emergent macrophytes expanded in the

Figure 4 A diagrammatic representation of the aquatic ecosystem. The ecosystem includes the lake and the catchment. External factors affect both the catchment and the lake. Internal (autogenic) factors act in the catchment and the state of the catchment affects the lake. The lake is also affected by its own numerous internal factors. Modified from Birks HH, Battarbee RW, and Birks HJB (2000) The development of the aquatic ecosystem at Kråkenes Lakes, Western Norway, during the late-glacial and early Holocene—a synthesis. *Journal of Paleolimnology* 23: 91–114.

shallower water due to a combination of sediment accumulation and lake-level lowering during a dry climatic phase. Later, taxa of eutrophic conditions expanded (*Ceratophyllum*, *Potamogeton crispus*, *P. pectinatus*, *Zannichellia palustris*, and *Stratiotes aloides*) at the expense of the weakly competitive mesotrophic taxa *Nitella*, *Najas flexilis*, and *N. marina*. This change coincided with retting (soaking) of flax and hemp in the lake, especially between 800 and 150 BP (1150–1800 AD). At approximately 0 BP (1950 AD), submerged and emergent macrophytes disappeared from the macrofossil record and were recorded as absent in lake surveys. This switch to an alternative stable state (Scheffer et al., 1993) was probably triggered by light limitation by the mass of phytoplankton and floating-leaved *N. alba* that had increased in response to the ever-increasing nutrient load from farming and sewage. In Lake Søbygaard, central Denmark, the process has gone a stage further (Brodersen et al.,

2001). The macrofossil record shows that, as in Gundsømagle Sø, *N. alba* and *Potamogeton crispus* replaced submerged aquatics (mainly *Ceratophyllum*) in the early 20th century. After approximately 1970, no submerged macrophytes were recorded and *N. alba* became sparse. Today, the shallow water is turbid with suspended phytoplankton and submerged macrophytes are absent.

A multiproxy paleolimnological investigation of the eutrophicated Lake Sallie in North Dakota, USA (Birks et al., 1976) revealed stages in its eutrophication that coincided with urban and agricultural development and sewage treatment. After European settlement in 1870, macrofossil analysis showed that a hard-water flora dominated by *Chara* and *Najas flexilis* was replaced by increasing quantities of *Ceratophyllum demersum* as phosphate increased, followed by *Potamogeton* spp. and *Ruppia maritima*, characteristic of high-conductivity lakes, until

a dense macrophyte growth prevailed, coarse fish replaced the game fish, H₂S evolved from the anaerobic sediments, and cyanobacteria blooms dominated the phytoplankton in summer. These changes occurred in 100 years between European settlement and 1970 when the core was taken.

Rapid changes during the past century were also documented in nine North African lakes and lagoons (Birks et al., 2001) within the multidisciplinary CASSARINA Project (Flower, 2001). The lakes in Morocco and Tunisia were impacted by the withdrawal of freshwater for agriculture and

cities. However, in the Nile Delta, Egypt, the seasonal Nile flood was progressively controlled by dams, leading to a year-round supply of freshwater. The paleolimnological sequence from Edku Lake ([Figure 11](#)) shows natural variations in salinity before ca. 1940. Macrophytes and freshwater molluscs, including biharzia-carrying *Biomphalaria alexandrina*, expanded rapidly after 1964. Eutrophication was aggravated by the introduction of nitrogen-fixing *Azolla filiculoides* in 1992. The ecosystem has been further modified by the spread of a floating blanket of *Eichhornia crassipes* (water hyacinth).

Figure 9 The distribution of plant macrofossils in the profile from Skateholm-Järvallen, southern coast of Skåne, southern Sweden, with the taxa arranged in order of similar occurrence, grouped into past assemblages A–G, and compared with phytosociological associations. The modern ecological requirements of the taxa for summer temperature (T°), water trophicity, and water depth are shown as well. Macrophyte taxa are shown with an asterisk. From Gaillard M-J and Lemdahl G (1988) Plant macrofossil analysis (seeds and fruits) at Skateholm-Järvallen, southern Sweden—A lagoonal landscape during the Atlantic and early Subboreal time. In: Larsson L (ed.) *The Skateholm Project I. Man and Environment*, pp. 34–38. Stockholm: Almqvist & Wiksell.

Plant macrofossils formed the basis of the aquatic ecosystem reconstructions in the CASSARINA Project. Detrended correspondence analyses of the sequences (Birks and Birks, 2001) showed unprecedented amounts of ecosystem turnover within 100 years in all the lakes, much more than any paleolimnologically documented natural rates of change. As the external stresses are maintained, the rates of change are increasing, emphasizing the pressures on wetland ecosystems in arid countries.

The Contribution of Macrofossil Analysis to Studies of Past Lake-Level Changes

Plant macrofossils provide the most useful biostratigraphical data for reconstruction of former lake-level changes because the distribution of macrophytes depends mainly on water depth. In some species, the water-depth range is sufficiently narrow to determine water-level changes, but most species have relatively broad ranges (Figure 1). Water chemistry and

Figure 10 Plant macrofossils from Lake Gundsømagle, Zealand, Denmark. (a) Submerged and floating-leaved aquatics. (b) Emergent aquatics. Concentrations in 100 cm³ of sediment. Note: The curve for *Cannabis* type is a pollen percentage curve (percentages as dark silhouettes; values exaggerated 10 times as lines). The diagrams are plotted on a depth scale with time as a side axis. (c) 1, Sediment accumulation rate (SAR) of minerogenic matter (proxy for soil erosion) and nonarboreal pollen (NAP) (proxy for open land); 2, summary of total number of macrofossil remains of submerged aquatics; 3, summary of total number of macrofossil remains of floating-leaved aquatics; and 4, summary of total number of macrofossil remains of emergent aquatics. The diagrams are plotted on a horizontal timescale. From Rasmussen P and Anderson NJ (2005) Natural and anthropogenic forcing of aquatic macrophyte development in a shallow Danish lake during the last 7000 years. *Journal of Biogeography* 32: 1993–2005.

nutrient status must also be considered when interpreting water-level changes (Figure 2). Water-level changes have climatic significance if they are determined by temperature and precipitation changes.

Most emergent species (Figure 3) tolerate interannual water depth fluctuations of 1 m but do not grow in water deeper than 1 m. *Schoenoplectus lacustris* and *Phragmites communis* may occupy the shoreline or the sublittoral zone (Figure 3) outside the *Nymphaea*–*Nuphar* zone. Sublittoral species generally have broad water-depth ranges, favoring deeper water (Figure 1). *Nymphaea alba*, *Najas marina*, and *Nuphar lutea* prefer water depths of 0.5–2.0 m, whereas *Myriophyllum spicatum*, several *Potamogeton* species, Characeae, and *Ceratophyllum demersum* frequently grow in 6 m of water (10 m for *Ceratophyllum*).

The overlap of habitats for most species listed in Figure 1 means that the results from a single core are difficult to interpret unequivocally in terms of water-depth fluctuations. However,

within one lake at a given stage in its development, depth ranges of the macrophytes should be relatively consistent. Thus, fluctuations in abundance and composition in the stratigraphical macrofossil record at a littoral coring point should primarily reflect spatial movements of vegetation belts and, therefore, changes in water depth. This phenomenon has been demonstrated in several European and North American lakes (Hannon and Gaillard, 1997). Movements of vegetation zones are most easily detected in shallow, species-rich eutrophic and mesotrophic lakes (Figure 3) (Hannon and Gaillard, 1997).

The spread of macrophytes toward the center of the lake may result from lake-level lowering or from sediment accumulation. In a single core, the plant macrofossil record of these two processes is often indistinguishable. Therefore, analyses of a transect of cores perpendicular to the shoreline is essential for reliable lake-level interpretations (Gaillard, 1984b; Digerfeldt, 1986). In addition, sediment accumulation can be

Figure 11 A plant and animal macrofossil diagram through recent sediments in Edku Lake, the Nile Delta, Egypt. Approximate ages are shown on the left and inferred water-quality changes are shown on the right. The timing of dam constructions is shown in blue. Data from Birks HH, Peglar SM, Boomer I, Flower RJ, and Ramdani M (2001) Palaeolimnological responses of nine North African lakes in the CASSARINA Project to recent environmental changes and human impact detected by plant macrofossil, pollen, and faunal analyses. *Aquatic Ecology* 35: 405–430.

Figure 12 The recommended methodology for reconstruction of past lake-level changes—that is, a combination of evidence inferred from

distinguished from a lake-level lowering by changes in the level of the sediment limit (Figure 12) (Gaillard and Digerfeldt, 1991). The use of several cores also enables changes in water depth to be distinguished from effects of chemistry and nutrient status changes (Digerfeldt, 1986; Hannon and Gaillard, 1997). This is particularly important when records of past lake-level changes are used as proxy records of past climate (humidity) change.

the analysis of a series of cores taken on a transect perpendicular to the shore toward the center of the lake. The most useful evidence is inferred from the core sediment stratigraphy—and the identification of the ‘sediment limit’ for various time periods—and from the plant macrofossil record. The figure shows the effects of lake-level changes on the distribution of shore vegetation, the level of the ‘sediment limit’ (boundary between organic and pure minerogenic sediments), and sediment composition. (a) The outward spread of the lake vegetation is determined primarily by water depth, and the level of the sediment limit is determined by exposure. The content of coarse minerogenic and organic matter in the sediment decreases outwards from the shore. The schematic diagram on the right shows the macrofossil and sediment composition in core 3. (b) A lowering in lake level will cause a lowering of sediment limit and erosion of the marginal sediment. As recorded in the schematic macrofossil diagram, the lowering will also result in an outward spread of the lake vegetation and an increase in the content of coarse matter in core 3. (c) A subsequent rise in lake level will produce a rise in the sediment limit, an inward displacement of the lake vegetation, and a decrease in the content of coarse matter in core 3. From Gaillard M-J and Digerfeldt G (1991) Palaeohydrological studies and their contribution to paleoecological and paleoclimatic reconstructions. *Ecological Bulletin* 41: 275–282.

Figure 13 Simplified plant macrofossil diagrams from sites investigated for lake-level changes in Europe (Sweden) and the United States (Minnesota), showing successions interpreted in terms of lake-level changes. The interpretation in terms of lake-level changes (shown at the right of each diagram) is inferred from the original publications and the syntheses published by Gaillard and Digerfeldt (1991). The diagrams are plotted against timescales. a, acutus; aquat, aquatilis; Equiset, Equisetum; eur, europaeus; flex, flexilis; fl, fluviatile; lac, lacustris; lat, latifolia; lut, lutea; m, mariscus; Menyanth, Menyanthes; Myrioph, Myriophyllum; panic, paniculata; Schoenopl, Schoenoplectus; spic, spicatum; trif, trifoliata; v, validus; LG, Late Glacial. The movement of macrophyte zones toward the shore can only be interpreted as a rise in lake level. Note, however, that increased exposure in large lakes may cause a similar change. This is one reason why not all lakes are suitable for lake-level studies.

Figures 13 and 14 show examples of two major types of Holocene plant macrofossil successions associated with lake-level changes (Hannon and Gaillard, 1997): (1) the ideal succession of sublittoral species followed by eulittoral species (or vice versa) (Vielångan I and II, Torreberga I and II, Trummen,

Bjäresjön I and II, Kumlan I and III, Upper Grave lake, and Almora Lake) and (2) the simultaneous increase (or decrease) of all lakeshore plants (eulittoral and sublittoral) (Krageholmssjön II, Bökeberg, and Kumlan II). The first type of record is the most elegant demonstration of a change in water depth at the coring point, but the second type is also useful. A reduction in abundant macrophytes remains indicates that the lakeshore is situated further from the coring point (Figure 15).

Figure 14 Simplified plant macrofossil diagrams from sites investigated for lake-level changes in Europe (Sweden) and the United States (Minnesota), showing successions interpreted in terms of lake-level changes. The Role of Macrofossils in Elucidating Causes of Paleolimnological Changes—Hypothesis Testing

Usually, the causes of paleolimnological change are inferred from the data in a ‘narrative’ way (e.g. the causes of eutrophication). Alternative factors are rarely tested. Within a well-designed multiproxy study, hypotheses about the causes of paleolimnological change can be made from part of the data set and tested against an independent part of the data set.

This novel approach was used in a multiproxy study of Holocene paleolimnology at Sägistalsee, Swiss Alps ([Lotter](#)

and [Birks, 2003](#)). The lake is at the present treeline, an important ecotone where the vegetation physiognomy changes. Changes in treelines and tree species limits can be detected in a sediment record using macrofossils. All the Sägistalsee proxies were recorded on one core, thus avoiding problems of multiple-core correlation. Principal components analysis was used to summarize the changes in all the proxies. Plant macrofossils were used to reconstruct vegetation changes in the catchment as well as in the lake, particularly the occurrence of trees and grazing indicators.

Table 2 Significance of the responses by terrestrial pollen and lake proxies to the predictors, climate and catchment vegetation, during the Holocene at Sägistalsee^a

'Responses' (proxies)	Scale	Is climate a significant predictor?	Is catchment vegetation a significant predictor?
Terrestrial Pollen	Catchment and regional	Y	Y
Macrofossils	Catchment	—	—
Lake biota			
Chironomids	Lake	N	Y
Cladocera	Lake	N	Y
Lake abiotic proxies			
Sediment grain size	Lake	—	Y
Magnetic parameters	Lake	—	Y
Geochemistry	Lake	—	(Y)

^aClimate parameters used were the insolation curve, the central European cold phases, and the Atlantic IRD record. The macrofossil record was used to reconstruct catchment vegetation. Statistically significant positive relationships are indicated by Y and significant negative relationships by N. Nonsignificance is indicated by dashes. Geochemistry was only slightly significantly related to catchment vegetation (Y). The most influential catchment changes were the development of closed *Picea* forest and stable soils and the forest clearances and catchment use by Bronze and Iron Age people. Results are from Lotter AF and Birks HJB (2003) The Holocene paleolimnology of Sägistalsee and its environmental history—A synthesis. *Journal of Paleolimnology* 30: 333–342.

Changes in a lake ecosystem can result from autogenic changes or changes in its catchment. Both can be affected by external factors, particularly climate or human activity (Figure 4). Two hypotheses were tested at Sägistalsee that might explain the Holocene paleolimnological changes: (1) Climate exerted significant control and (2) catchment vegetation changes have been a major influence. The macrofossil record was used as the basis for the catchment vegetation reconstructions. The Holocene climate factors used were the insolation curve, the central European cold phases, and the Atlantic ice-rafted detritus record. The summarized responses of the other proxies were tested against the two predictors using partial redundancy analyses and restricted Monte Carlo permutation tests. The results (Table 2) showed that climate had no significant effect on lake variables, but that it did influence regional vegetation development inferred from pollen data. In contrast, the catchment vegetation was a significant predictor for all the lake variables except geochemistry, influencing grain size and magnetism (which reflect soil stabilization and erosion) and dominating the effects on the lake biota.

This study showed how intimately a lake is linked to its catchment. It also demonstrated the key role played by plant macrofossils within this multiproxy study. The hypothesis-testing approach will undoubtedly become more widespread in paleolimnology in attempts to determine the factors influencing lake ecosystem changes.

Introduction

The study of Pleistocene terrestrial environments has tended to focus mainly on the middle and high latitude regions where water-lain deposits (lake sediments, peat bogs, fluvial deposits) tend to be well preserved. By their very nature, most desert and semi-arid regions offer few if any archives of waterlain sediments for such studies. However, an important, if unexpected archive of Pleistocene desert environments does exist, in the form of rodent middens. Rodent middens are produced by *Neotoma* (packrats) and *Erethizon* (porcupine) in North America; *Lagidium* (viscacha), *Phyllotis* (leaf-eared mice), *Abrocoma* (chinchilla rats) and *Octodontomys* (mountain degu) in South America; *Procavia* (rock hyrax) and *Petromus* (Dassie rat) in Africa and the Middle East; *Alticola* (mountain voles) and *Ochotona* (pikas) in central Asia, and *Leporillus* (stick-nest rats) in Australia. The studies of South American middens have mostly concerned pollen analysis, although a few plant macrofossil records have been developed (Betancourt et al., 2000; Latorre et al., 2002). The studies of hyrax middens from the Middle East and desert regions of Africa have focused mainly on pollen (Scott and Vogel, 2000). The few studied Stick-nest rat middens in Australia are all of late Holocene age (Pearson, 1999). Little research has been done on porcupine middens in North America, although these middens are known to persist as long as 25 000 years in arid conditions (Betancourt et al., 1986). The middens of North American packrats have yielded by far the most well-studied records of late Pleistocene plant macrofossils. This article focuses primarily on this remarkable record.

North American Packrat Middens

Packrats, or woodrats, are the native North American rats of the genus *Neotoma* (Figure 1). There are 21 species in this genus. These rats are broadly distributed, ranging from Arctic Canada to Nicaragua. They are a very successful group, and only a few species inhabit desert and semi-arid regions. While packrats are not strict herbivores, plants are by far the most important part of their diets. Packrats live in dens. Regardless of size, each den is occupied by one individual, or the female and her young. These dens range from piles of sticks under shrubs or trees to more elaborate shelters in caves and rock shelters. In the arid Southwest, these dens often include tightly-packed bundles of cactus stems that deter predators. Besides bedding material and food plants, packrats also accumulate other objects from the surrounding landscape. These objects, plus packrat feces, are cemented together by successive layers of dried rat urine to form a midden (Figure 2). The crystalized urine layers encapsulate plant materials and rat feces to form a hardened mass,

called amberat. When protected from direct rainfall and high humidity, amberat is extremely resistant to decomposition. It secures biological specimens (plant parts, bones, insects, etc.) into a kind of desiccated time capsule, documenting the ancient life of the region. Middens of late Holocene age have been found throughout the western United States and southwestern Canada (Hebda et al., 1990). In the arid regions of the southwestern United States and northern Mexico, many packrat middens have remained intact beyond the limit of the radiocarbon dating method (>45 000 years).

Packrat ecology has been described by Vaughan (1990). Packrats require succulent plants for food, and they must have shelter, as they do not have the metabolic mechanisms for water retention found in some other rodents. The dens are often built in rock shelters, crevices, and caves, where there is a microclimate that is significantly buffered from ambient climatic conditions. The annual variation of temperatures in packrat dens from mid- to high latitudes is as little as 15 °C. Packrat middens accumulate as long as a den is occupied. In sheltered localities, these middens may accumulate for millennia, as favorable denning sites are inhabited by succeeding generations of packrats. Packrat middens are an unusual source of fossils, because the packrat is the primary agent that accumulates the materials found in middens. They eat a wide variety of plants, and the unconsumed pieces of these plants eventually form the bulk of the plant macrofossils in midden records. Because of the rodent's food preferences, plant macrofossil records from middens do not represent the full spectrum of regional vegetation; nevertheless, the variety of plant species found in these assemblages can be truly remarkable. Dial and Czaplewski (1990) discussed the problems of potential bias in packrat midden plant macrofossil assemblages. Their study concluded that if several middens are studied from a given region, then the contemporaneous plant species diversity of that region may be fairly represented in the suite of midden samples. A study of paired samples of modern vegetation communities and paired samples of ancient communities was used to investigate the probability that the absence of a plant taxon from a packrat midden implies absence from the ancient plant community where the packrat lived (Nowak et al., 2000). The probability of the occurrence of a false inference was calculated to be from 7–11%, depending on the taxon. Lyford et al. (2004) studied the contents of 59 modern packrat (*Neotoma cinerea*) middens in escarpments and canyons in three states in the Rocky Mountain region. They found that these middens are highly reliable sensors for the presence of key woody plant species, such as *Juniperus osteosperma* (Utah juniper) and *J. scopulorum* (Rocky Mountain juniper), but that other conifers were occasionally absent from modern middens if their presence in the local vegetation cover was less than 20% of the canopy cover.

How Middens Are Analyzed

Packrat midden analysis methods have been described by Spaulding et al. (1990). Most ancient packrat middens are indurated (hardened almost to the consistency of rock), and resemble blocks of asphalt. Amberat forms a tough, outer rind that resists erosion and decomposition (Figure 1). When moist, amberat is sticky. It is this stickiness that often cements middens to the walls of caves or rock shelters. Midden samples are taken by the removal of discrete horizontal sections of midden, often using hammers and chisels. Each sample is radiocarbon-dated, because successive layers in a midden may have been deposited at widely-spaced time intervals, or occasionally in random order. Radiocarbon dates are often obtained from packrat fecal pellets, or from plant macrofossils. The majority of middens are of Holocene and late Wisconsin age (Figure 3).

Following rehydration in a laboratory, the samples are wet-screened to remove fine sediment, then dried and sorted under

Figure 3 Distribution of radiocarbon ages of packrat middens from the southwestern United States and northern Mexico, after Thompson et al., 2004.

a low-power microscope. The plant macrofossils are picked out and sorted from this dried matrix. Macrofossils from individual species of plants are sometimes submitted for AMS radiocarbon dating (see AMS Method).

Plant macrofossils from middens are frequently identified to the species level. Midden plant macrofossil analysis is generally done on a presence/absence basis for each identified taxon. Occasionally, a subjective quantification of the remains is conducted, either through application of a relative abundance scale (rare, common, etc.), or through specimen counts and dry weights of materials. The results of plant macrofossil analyses are often tabulated in terms of relative species abundance. They are separated into categories such as rare, common, abundant, and very abundant.

Distribution of Fossil Sites in the Arid Southwest

Figures 4 through to 7 illustrate published packrat midden records from southwestern North America. Dozens of sites have been studied in each of the major desert regions discussed below, and more than a thousand radiocarbon dates have been obtained from regional midden samples. Most of the midden samples discussed here have been taken from canyons and rocky hillsides, just above the desert floor. In the American Southwest, no Pleistocene middens have been sampled at elevations greater than 2500 m. The elevational distribution of midden samples reflects regional physiography. Sites south of 36° latitude generally occur at elevations below 1500 m, while more northerly sites reflect a broader range of elevations.

Figure 4 Map of the Chihuahuan Desert region, showing location of packrat middens from which fossil analyses have been published (triangles).

Regional Studies

Chihuahuan Desert

The Chihuahuan Desert is an interior continental desert, stretching from southeastern Arizona in the northwest to northern Zacatecas, Mexico in the southeast (Figure 4). The desert lies in the rainshadow of the Sierra Madre Occidental to the west and the Sierra Madre Oriental to the east. Sub-freezing temperatures are not uncommon in winter, and Arctic air mass incursions may bring very cold weather to even the southernmost parts of the desert. Today the southern Chihuahuan Desert supports subtropical vegetation, rich in succulent scrub species. This flora diminishes to the north, giving way to more cold-tolerant desert grassland. The plant macrofossil record developed from Chihuahuan Desert packrat middens reveals a series of environmental changes through the late Pleistocene and the Holocene. These changes brought about major shifts in plant distributions, both within the desert (i.e., elevational shifts) and beyond its boundaries (i.e., regional extirpations and the invasion of new species). The plant macrofossil samples studied from this desert range in age

from >43 300 years BP to recent. Regional plant macrofossil records are discussed by Van Devender (1990a).

In the northern Chihuahuan desert, pinyon-juniper-oak woodland dominated limestone slopes during the middle to late Wisconsin interval (42 000 to 12 750 cal years BP). At the northern edge of the desert (Rough Canyon, New Mexico), Rocky Mountain juniper (*J. scopulorum*) began to decline at 14 000 cal years BP, as Holocene warming started and it was regionally extirpated by 12 400 cal years BP (Betancourt et al., 2001). An early Holocene oak-juniper woodland was replaced by desert-grassland after about 9250 years BP. At Rough Canyon, elements of the modern desert vegetation began dominating packrat midden floras after 5750 years BP (Betancourt et al., 2001). By about 4700 cal years BP, the common elements of the Chihuahuan Desert flora had become established throughout the northern Chihuahuan Desert region, forming a relatively modern desert-scrub vegetation on rocky slopes. This vegetation continues to be regionally dominant today.

In the central Chihuahuan Desert, in and around Big Bend National Park, Texas, the middle Wisconsin vegetation (40 000–26 500 years BP) was a pinyon-juniper-oak

woodland on the uplands, and juniper grassland on the lowlands. By late Wisconsin times (prior to 25 000 years BP), papershell pinyon (*Pinus remota*) became important in the upland flora, and pinyon-juniper-oak woodland spread into lowland regions, indicating relatively mild winters, cool summers, and greater precipitation than today. The boundary between late Wisconsin and early Holocene environments (between 13 100 and 12 100 cal years BP) is well marked in the vegetation, with the demise of papershell pinyon and increase of shrub oak (*Quercus pungens*) before 9200 cal years BP, followed by a succulent desert-scrub vegetation, including lechuguilla (*Agave lechuguilla*), catclaw acacia (*Acacia greggii*), honey mesquite (*Prosopis glandulosa*), and prickly pear cactus (*Opuntia* spp.). Vegetation diversity increased in the mid-Holocene, signaling the shift to subtropical climatic conditions. More mesic vegetation communities developed here in the last 1000 years. By the middle Holocene, the vegetation in the lowlands of Big Bend was essentially modern desert-scrub.

In the southern Chihuahuan Desert of Mexico, the late Wisconsin vegetation on limestone slopes was a woodland dominated by juniper and papershell pinyon in association with succulents such as sotol (*Dasyllirion*) and beaked yucca (*Yucca rostrata*). Pinyon pine declined after 16 000 cal years BP, as succulents increased. Between 13 600 and 10 550 cal years BP the regional vegetation shifted to Chihuahuan desert-scrub. The paleobotanical record from this region shows unique combinations of floristic elements. Late Glacial floras included both conifers and desert succulents, but macrofossils of temperate plants disappeared from regional records during the middle and late Holocene. A mosaic of temperate and xeric habitats has been available to the regional biota, even during the last 1000 years, when other regions of the Chihuahuan Desert have experienced extremes of aridity.

Sonoran Desert

This desert comprises the arid, subtropical region centered around the head of the Gulf of California (Figure 5), encompassing parts of Sonora and Baja California in Mexico, and southern Arizona and California in the United States. All parts of the Sonoran Desert are occasionally subject to winter freezes, although rarely for more than one night at a time. Most of the large, columnar cacti that characterize the Sonoran Desert are not able to tolerate prolonged freezing. Rainfall ranges from a bi-seasonal pattern with summer monsoon moisture in Sonora and Arizona to a winter rainfall pattern along the west coast of Baja California. Changes in large-scale atmospheric circulation patterns during the Wisconsin glaciation caused changes in Sonoran Desert regional climates, especially in precipitation patterns and the frequency of winter freezes.

Unlike the Chihuahuan Desert, the plant macrofossil record from Sonoran Desert packrat middens indicates that regional vegetation succession from the late Wisconsin through the Holocene made a single, continuous progression toward modern plant communities. The regional paleobotanical record has been summarized by Van Devender (1990b). The chronological sequence of plant communities during the last 20 000 years is similar to the modern vegetational gradient from the tops of mountains to valley floors. This history is summarized in Table 1. Central and southern Arizona were clothed with a variety of woodlands in the late Wisconsin. In upland regions, juniper or juniper-oak woodlands persisted until the early Holocene. Juniper died out in the Sonoran Desert after 10 000 cal years BP. The vegetation of lowland Sonoran regions has been desert-scrub since the early Holocene. Desert-scrub communities, including species found today in the Mojave Desert, persisted in the harsh lowlands of the lower Colorado River valley throughout the late Pleistocene. It is thought that this region may have served as a refuge for North American desert plants for much of the Quaternary. Typical Mojave Desert species migrated north along the Colorado River and crossed over it only during the warmest (interglacial) periods. The ecotone (ecological boundary) between the Sonoran and Mojave Deserts has essentially remained in its current position since 10 000 cal years BP. After 4500 cal years BP, modern vegetation became established throughout the Sonoran Desert.

Based on the plant macrofossil evidence, late Wisconsin climate in the Sonoran Desert had cooler-than-modern summers and a dominance of winter precipitation. While winters may have been generally cooler, it appears that freezing conditions were actually rarer than today, a remarkable finding, given the degree of climatic cooling associated with North American glacial climates in regions further north. Early Holocene Sonoran climates were transitional between late Wisconsin and modern climates. Regional summer temperatures probably remained cooler, based on the persistence of conifers in the uplands. Parts of south-central Arizona received up to 30% more precipitation than today in the early Holocene. A relatively modern climate was established after 10 000 cal years BP, characterized by hot summers. Mid-Holocene plant macrofossil assemblages indicate greater species richness than today, probably because of increased rainfall. While the packrat midden

Figure 5 Map of the Sonoran Desert region, showing location of packrat middens from which fossil analyses have been published (triangles).

Table 1 Summary of Changes of Sonoran Desert Vegetation Inferred from Packrat Midden Data (after Elias, 1995)*Region time interval vegetation***Central Arizona**

Uplands late Wisconsin Pinyon-juniper-oak woodland (550–1550 m)

Early Holocene Juniper-oak woodland with Sonoran desert-scrub

Late Holocene Sonoran desert-scrub with increasing subtropical elements

Lowlands late Wisconsin Juniper woodlands and/or Mohave desert-scrub (<600 m)

Early Holocene onwards Sonoran desert-scrub

Southern Arizona

Uplands late Wisconsin Pinyon-oak-juniper woodland with Joshua tree (550–1550 m)

After 13 000 cal years BP Xeric juniper woodland with shrub oak or chaparral

After 10 000 cal years BP Juniper disappears from entire region

Lowlands late Wisconsin Xeric juniper woodland with Joshua tree, yucca, beargrass (600–300 m)

Early Holocene desert-scrub common

After 4500 cal years BP Modern Sonoran desert-scrub

Baja California

Lowlands early Holocene abundant Boojam tree; buckwheats and Mormon tea (0–400 m) in desert-scrub community

Late Holocene Boojam tree less abundant; buckwheats and Mormon tea disappear; increasing succulents

Table 2 Summary of Changes of Mojave Desert Vegetation Inferred From Packrat Midden Data (after Elias, 1995)*Region time interval vegetation***Southern and Central Mojave**

Lowlands late Wisconsin Juniper woodland (<1000 m)

Early Holocene desert-scrub widespread by 11 500 cal years BP; succulents and grasses increasing

Uplands late Wisconsin Juniper-pinyon woodland (1000–1800 m)

Early Holocene Woodland persists at higher elevations and moist slopes

Mid-Holocene desert-scrub rich in species

Late Holocene downward shift of blackbrush desert-scrub

Northern Mojave

Uplands late Wisconsin desert-scrub in dry locations, with Mormon tea, shadscale, (1000–1800 m) rubber rabbitbrush, and snowberry; juniper woodland in most regions; at higher elevations, limber pine in drier sites and white fir in mesic sites

Early Holocene Woodland persists on some slopes; after 8700 cal years BP, then replaced by creosote bush and Joshua tree scrub

Mid-Holocene desert-scrub lacking in diversity

Late Holocene rich desert-scrub communities at lower elevations and pinyon-juniper woodlands at higher elevations

**Figure 6** Map of the Mojave Desert and Great Basin regions, showing location of packrat middens from which fossil analyses have been published (triangles).

results are internally consistent throughout the Sonoran Desert, none of the regional paleoclimatic reconstructions based on these fossil data have supported the results of general circulation model simulations for the early and middle Holocene (Van Devender et al., 1994). By 4500 cal years BP, a completely modern climatic regime was established in the Sonoran Desert.

Mojave Desert

The Mojave is a small, topographically complex desert, situated in southern Nevada and adjacent California and Arizona

(Figure 6). The modern vegetation of the southern Mojave Desert (south of 36° N latitude) is dominated by creosote bush (*Larrea divaricata*), white bursage (*Ambrosia dumosa*), and pygmy-cedar (*Peucephyllum schottii*). The northern Mojave region is generally higher in elevation, and the modern vegetation here is a temperate desert-scrub, including blackbrush (*Coleogyne ramosissima*), Joshua tree (*Yucca brevifolia*), ground-thorn (*Menodora spinescens*), boxthorn (*Lycium* spp.), and goldenbushes (*Haplopappus* spp.). The higher mountains in southern Nevada support pinyon-juniper woodlands above 1800 m elevation, giving way to fir-pine forest above 2200 m. Bristlecone pine (*Pinus longaeva*) dominates subalpine landscapes above 2700 m.

The late Wisconsin and Holocene vegetation history of the Mojave Desert has been discussed by Spaulding (1990, 1995), and is summarized in Table 2. The northern Mojave region has yielded more packrat midden studies than the southern region. During the late Wisconsin period, woodlands extended down-slope on to the Mojave lowlands. These were 'pygmy' woodlands, composed primarily of juniper (mixed with pinyon pine at elevations below 1500 m), shrub oak, and Joshua tree in some regions. During the Last Glacial Maximum in the northern Mojave, elevations above 1600 m had populations of limber pine (*Pinus flexilis*), replaced at times by white fir (*Abies concolor*). The lower reaches of the Grand Canyon lie in the southeastern corner of the Mojave Desert. During the late Wisconsin, this region supported more succulent species, including barrel cacti and yuccas.

By 11 600 cal years BP, a major shift in Mojave vegetation was underway: desert-scrub vegetation spread across the lowlands, at the expense of semi-arid woodland. However, the transition from glacial to postglacial vegetation was not smooth; it was marked by multiple incursions of new taxa and extirpations of others. Not all of the newly invading species remained throughout the Holocene. The immigration of warm-adapted species from their southern refugia took place in stages. On the other hand, widespread desert vegetation

apparently developed earlier in the Mojave than in the Sonoran or Chihuahuan deserts, with the earliest occurrences documented from middens dating to 18 000 cal years BP. By 8600 years BP, woodlands had been replaced by desert vegetation throughout the lower elevations of the Mojave. An interval of increased aridity is marked by vegetation changes in most regions of the Mojave during the mid-Holocene, but regional packrat midden evidence suggests that effective moisture subsequently increased between 4200 and 1400 cal years BP. This increase was probably due to a combination of increased precipitation and decreased temperatures. Conifers retreated up mountain slopes in the Mojave region during the last 1400–500 years, signaling a return to hotter, drier conditions.

Great Basin

The Great Basin is a large, arid region between the Rocky Mountains and the Sierra Nevada (Figure 6). This enormous, closed basin is made up of broad valleys of sagebrush steppe, dissected by more than one hundred narrow mountain chains that trend north to northeast. During the last glaciation, immense lakes covered the Great Basin lowlands, and glaciers flowed down from high mountain valleys. In the modern vegetation, sagebrush and shadscale (*Atriplex confertifolia*) dominate the low elevation steppe vegetation. Pinyon-juniper woodland covers most low mountain slopes in the southern two-thirds of the region, while juniper woodland characterizes the northern third. Montane forests of ponderosa pine (*Pinus ponderosa*), white fir, and Douglas fir grow in the mountains of the eastern and southern sectors. The montane zone in the central and northern Great Basin is covered by sagebrush grassland. Some isolated mountain ranges are covered by mountain mahogany (*Cercocarpus*) woodland. Sub-Alpine forests of bristlecone pine, limber pine, and Englemann spruce (*Picea engelmannii*) occur in the higher mountain ranges, and small pockets of Alpine tundra grow on isolated peaks.

The late Pleistocene and Holocene vegetational history of the Great Basin has been discussed by Thompson (1990), and is summarized in Table 3 (see Western North America). Many plant species that lived in the Great Basin during the Pleistocene have their northern limits today in the Mojave Desert; other plants grew as much as 1000 m downslope from their modern ranges. Unlike some other deserts, there is no evidence that extra-limital plant species immigrated into the Great Basin during the late Pleistocene. Instead, regional floras suffered a reduction in species diversity, as many of the modern taxa were absent.

The packrat midden records show that sub-Alpine conifers, especially limber pine, expanded their ranges downslope by as much as 1000 m during the late Wisconsin interval. Curiously, the modern dominants of the montane zone (spruce and fir) were absent from the region during much of the late Pleistocene. Many persisted south of the Great Basin, in southern Nevada and southeastern California. In the western Great Basin, juniper dominated lower elevation woodlands in areas adjacent to pluvial lakes. Although Utah juniper (*Juniperus osteosperma*) was likely the dominant species at these sites, possible hybrids of western juniper (*Juniperus occidentalis*), Rocky Mountain juniper (*Juniperus scopulorum*) and California juniper (*Juniperus californica*) have been found in some

Table 3 Summary of Changes in Great Basin Vegetation Inferred From Packrat Midden Data (after Elias, 1995)

Time interval vegetation

Late Wisconsin (26 000–17 000 cal years BP)

Uplands:

Sub-Alpine conifers grow as much as 1000 m downslope from modern limits; dominant trees: bristlecone pine, limber pine, prostrate juniper, and Englemann spruce in some locations; many shrubs and trees common today are absent, including Douglas fir, white fir, and Rocky Mountain juniper.

These shift south, into the Mojave Desert and elsewhere

Steppe regions:

Sagebrush and other steppe species present across entire range of elevations in Great Basin, up to sub-Alpine (as ground cover under coniferous forests).

Steppe species include sagebrush, rabbitbrush, horsebrush, snake-weed, and snowberry steppe species spread south into Mojave and Sonoran deserts, and other regions.

Late Glacial (17 000–11 500 cal years BP)

Limber pine, prostrate juniper, Englemann spruce, and some shrubs decline from 16 000–13 000 cal years BP, replaced by snake-weed, rock spiraea Bristlecone and limber pine persist at late Wisconsin levels until after 11 500 cal years BP

Mesic-adapted plants at many elevations replaced by thermophiles starting at 16 000 cal years BP In southern Great Basin, a major shift to desert vegetation before 13 000 cal years BP

Early Holocene (11 500–7800 cal years BP)

Bristlecone and limber pines absent from western Utah and eastern Nevada by 9600 cal years BP. Limber pine and Douglas fir replaced by Utah juniper and Gambel oak in southeastern Nevada by 10 000 cal years BP.

Mid-Holocene (7800–4500 cal years BP)

Rapid transition to modern vegetation zones between 7800 and 6900 cal years BP. Pinyon-juniper woodland established in several mountain ranges, characterized by Utah juniper and single-needle pinyon pine. Midden assemblages include a number of species that are rare or absent from Great Basin today.

Late Holocene (4500 cal years BP–present)

Few changes in regional vegetation. Ranges of sagebrush and shadscale steppe contract; upper treeline retreats to mid-Holocene levels Lower treeline drops about 170 m between 4500 and 2000 cal years BP, then retreats to modern levels during last 2000 years

middens. Sagebrush and other steppe species expanded their ranges in the late Wisconsin, both in latitude and elevation. They spread south to the Mojave and Sonoran deserts, and into adjacent mountain ranges. The drier regions of the northern Great Basin were dominated by shadscale.

The downslope extension of bristlecone and limber pines might have produced a contiguous forest zone stretching from the eastern shore of pluvial Lake Lahontan to the Rockies, but edaphic factors probably prevented conifer establishment in some regions. These vast coniferous woodlands became fragmented as lower treeline advanced upslope in response to climatic warming at the end of the last glaciation. The shift from Pleistocene to Holocene vegetation regimes took place in different ways at different sites. In the boundary region between the Mojave Desert and Great Basin, the major vegetation change took place by 13 000 cal years BP. In the north, this shift was completed between 10 000 and 7800 cal years BP.

The Great Basin has a large number of endemic grasses and other herbs. The packrat midden record suggests that this is due to a combination of factors. Range fragmentation led to genetic isolation and rapid evolution, at least at the subspecific level. Also, new habitats opened up as the huge pluvial lakes receded and climates changed at the end of the last glaciation. During

the Holocene, semi-arid lowlands have acted as biotic barriers, much as pluvial lakes did during the Pleistocene. Lyford et al. (2002) extended Holocene midden research into the northern edge of the Great Basin in southern Montana. They were able to document the timing of a regional shift from cooler and moister to hotter and drier climates, based on the replacement of boreal and montane juniper species by the Great Basin juniper, *J. osteosperma*. This replacement occurred by 4700 ^{14}C years BP, and was followed by another cool, moist interval (4400–2700 ^{14}C years BP) during which the lower treeline shifted downslope once again.

The Colorado Plateau

This plateau is a well-marked physiographic province that covers nearly 400 000 km² of the Four Corners region (Figure 7). Plateau elevations range from 1000 to 4600 m, with much of the plateau below 1800 m. Topography strongly affects regional climates, now and in the late Pleistocene. Modern vegetation zones are shown in Figure 8. These zones do not fall in simple elevation bands, because local bedrock type strongly affects the vegetation.

More than 180 packrat middens have been analyzed from sites on the Colorado Plateau. The middens occur only in regions with sandstone and limestone bedrock. The plant macrofossil record of the region has been discussed by Betancourt (1990) and is summarized in Figure 8. During the late Wisconsin, upper treeline on the Colorado Plateau was significantly depressed, and Alpine tundra regions may have supported more sage cover than is found there today. Today Alpine tundra is found in only three high mountain regions, at elevations above 3660 m. Late Glacial coniferous woodlands extended down to 2000 m elevation in

Figure 7 Map of the Colorado Plateau region, showing location of packrat middens from which fossil analyses have been published (triangles).

Figure 8 Diagrammatic drawing showing principal vegetation zones of the Colorado Plateau during late Wisconsin and modern times, after Betancourt, 1990.

Figure 9 Diagrammatic drawing showing principal vegetation zones of the Grand Canyon during Full Glacial, early Holocene, and modern times, after Cole, 1990b.

mesic canyon habitats. In the San Juan Mountains and Glen Canyon, coniferous woodlands with limber pine, Douglas fir (*Pseudotsuga menziesii*), junipers, and Colorado blue spruce (*Picea pungens*) grew down to 1300 m elevation on rocky sites. Regional lowlands (<1300 m elevation) were covered in desert-scrub with junipers and sagebrush.

Plant macrofossil records from the Grand Canyon indicate that the ranges of regional plant species are now 700–900 m higher and 400–700 km further upstream than they were in the late Wisconsin interval (Cole, 1990a) (Figure 9). Cole's (1985) work on the paleobotany of the Grand Canyon also suggested that plant migration lagged significantly behind climate change at the end of the last glaciation. For instance, the upslope immigration of some species to their modern zones was not completed until the mid-Holocene; some plants, such as ocotillo (*Fouquieria splendens*), may still be adjusting to past climate fluctuations. These assertions sparked a heated debate among paleobotanists (Markgraf, 1986; Cole, 1986). The unexpected associations of species in early Holocene plant macrofossil assemblages may be partly due to unique climatic conditions, involving the dynamics of monsoonal moisture and shifts in the timing of summer warmth. Betancourt (1990) suggested that the length and difficulty of the various migration corridors leading to the Grand Canyon may have played a significant role in the postglacial establishment of new species. Cole (1990a) concluded that the biological phenomena, rather than unusual climatic conditions, are the cause of the peculiar plant associations of the Grand Canyon in the early Holocene. In his view, 'as the complexities of plant population dynamics in the Grand Canyon become better understood, the biologically-oriented theories will gain ground.'

Major Implications of Packrat Midden Studies

The plant macrofossil record is providing valuable data on past and present ecosystems of the arid southwest. The fossil record shows that environmental change during the Pleistocene was substantial, even in regions such as the arid southwest that were far-removed from continental ice sheets. The midden record offers good evidence for individualistic responses to major climate changes that brought about uneven displacement of species, and anomalous associations in which some species do not appear to belong in the communities where they were found.

The age and origin of southwestern desert biological communities are important questions in the field of biogeography. About 1200 of the 5500 species of southwestern plants are considered endemic to that region, a far higher proportion than elsewhere in North America. Even though many of these plants evolved locally, the packrat midden data suggest that desert plant communities are very recent and very dynamic. One of the reasons the midden data are so important is that they offer tangible evidence of the history of species in this region. For instance, based on modern data, creosote bush was thought by some to have immigrated from South America during the Holocene. However, the fossil evidence shows that it grew at least as far north as the Arizona-Sonora border during the middle of the last glaciation. We are not currently able to verify the exact whereabouts of southern refugia for the desert biota in Mexico, because many regions hypothesized to have been refugia are now in the tropical or subtropical zones, where preservation of middens is extremely limited.

Many intriguing questions remain to be addressed by the plant macrofossil record. For instance, the late Wisconsin pygmy conifer woodlands that covered much of the lower elevations of the American Southwest remained intact until after 11 000 years. Was this long-term ecosystem stability a product of climatic stability across a wide region? What brought about the demise of the lowland woodlands? One way of approaching these questions is the analysis of stable isotopes from the cellulose preserved in woody plant macrofossils. In particular, analysis of changes in the concentration of the deuterium may help to clarify the climate regimes under which these plants grew, and to define the climatic changes that forced their retreat from the desert lowlands. Another difficult question concerns a major switch in pinyon pines at the end of the Pleistocene. Colorado pinyon (*Pinus edulis*) and single-needle pinyon (*Pinus monophylla*) became the dominant pinyon pine species in the Holocene, at the expense of papershell pinyon and another single-needle pinyon, *Pinus californiarum* var. *fallax*, that were dominant in the late Pleistocene. Why this reversal of roles? One approach to the problem of population dynamics of pinyon pines is through the study of ancient DNA. Gene amplification techniques are being applied to pinyon wood, cones, and needles preserved in middens, to unravel the genetic relationships between ancient populations and their modern descendants (Betancourt et al, 1991). Modern pinyon pine ranges are far from static. Both single-needle pinyon and Colorado pinyon are still migrating. The northernmost population of Colorado pinyon became established in north-central Colorado only 400 years ago. The same is true of single-needle pinyon, which arrived at its current northwestern limit near Reno, Nevada within the last 700 years.

Summary

The fossil record developed from packrat middens in the arid southwest is a unique resource for investigating the pace and direction of biotic changes. Indeed, without the packrat midden data, we would know little about the biotic history of this region where lake sediments are scarce and peat bogs almost non-existent. The midden data have shown that late Pleistocene landscapes of the southwest were radically different from today, with coniferous woodlands covering much of the lowland regions that now support only desert-scrub. This change was not just a downslope shift of intact communities; it brought together new associations of plants and animals in an ever-changing dynamic that is still at work today (Van Devender, 1985). Arid-land biotic communities viewed as 'stable' from our short-term perspective are actually in a constant state of flux. Each new environmental change brings a different cast of characters to the biological stage. In some regions, like the Great Basin, the same players appear in succeeding intervals. In other regions, such as the Sonoran and Chihuahuan deserts, new players appear from time to time, often at the expense of others. The fossil record has much to say to both the paleontological and modern ecological research communities; we are just starting to come to grips with its message.

Plant macrofossils preserved in lake sediment are frequently identified and counted as a means of reconstructing the vegetational communities of a lake and surrounding areas. However, many factors affect the relationships between macrofossil assemblages and plant communities. This article explores those factors and the types of studies that clarify them.

In an ideal system, each individual plant of a species would produce a standard quantity of preservable macrofossils. (The term macrofossil is here used to indicate identifiable plant parts that are large enough to be visible without magnification and have the potential to become incorporated into lake or peatland sediment.) These macrofossils would disperse in a predictable fashion, uniformly incorporate into sediment across a lake basin, and be lost to predators and decomposition in consistent proportions, all regardless of individual basin morphology. Macrofossil assemblages could then be used to reconstruct past vegetational communities by means of precise mathematical inference models for each macrofossil type, which might appear as follows:

$$V_A = (N_A \div (P_A - L_A)) \times D_A \times b \times S$$

where V_A is the proportion of local vegetation represented by plant taxon A; N_A is the number of macrofossil type A found in standard volume of sediment; P_A is the annual production of macrofossil type A; L_A is the mean annual loss from sediment of macrofossil type A by decomposition, predation, etc.; D_A is the mean dispersal distance from source plants for macrofossil type A; b is the basin coefficient accounting for basin characteristics such as fetch, wind direction, and slope; and S is the sample location within the basin.

Alas, natural systems do not work with mathematical uniformity but are notoriously quirky and constantly changing. An additional factor could be added to the previous formula:

U = all unknown factors that paleoecologists have not even begun to anticipate.

Macrofossils do not meet the first and most important requirement for quantitative paleoenvironmental reconstruction (Birks, 1995); they are not systematically (linearly or unimodally) related to the variable (proportion of a species within a vegetational community) of interest. Thus, macrofossils are more commonly called upon as qualitative indicators of past environments. Ecological conditions may be inferred based on the known ecological tolerances of species whose remains are found as macrofossils (indicator species approach), or vegetational composition may be reconstructed based on known community associations of multiple species represented in sediment (assemblage approach) (Birks and Birks, 1980).

Surface Sample Studies

Significance

Studies of surface sediment samples are unlikely to resolve the idiosyncrasies of individual macrofossil types to the extent that precise translation into former vegetational communities is possible. However, such studies are useful to determine what factors affect macrofossil deposition; which plant taxa are over-, under-, or not represented by macrofossils; what catchment is represented by the macrofossil assemblage; what type of lake is best suited for macrofossil analysis; what part of the lake should be cored for sediment collection; and so forth. Because of biases inflicted on macrofossil assemblages by many taphonomic effects, ancient macrofossil assemblages should be compared to modern macrofossil assemblages rather than to plant communities.

Review of Surface Sample Studies

Numerous studies of surface sediment macrofossils have increased the body of knowledge concerning macrofossil taphonomy and representation of vegetational communities. H. H. Birks conducted one of the earliest surface macrofossil studies (Birks, 1973). Her work set the standard for such studies, and her ongoing analysis and discussion of macrofossil work has significantly shaped the science (Birks, 2003; Birks and Birks, 2000).

Several studies have emphasized macrofossils generated by aquatic or wetland plant species. Birks (1973) analyzed sediment samples from 32 small lakes in Minnesota and studied the relationship between macrofossils and source vegetation with respect to distance between source plants and incorporation of macrofossils into sediment. Greatrex (1983) studied seeds and fruits found in fen, fen-carr, and swamp carr sediment in Great Britain. In an attempt to develop a mathematical model to infer past water depths from macrofossil assemblages, Dieffenbacher-Krall and Halteman (2000) analyzed surface sediment samples from numerous alkaline lakes in New England. Zhao et al. (2006) performed extensive sediment and vegetation sampling of a British lake to assess spatial patchiness of plant remains in relation to community structure. This study is particularly notable for the researchers' efforts to identify leaves of aquatic plant species that typically produce little seed and also for a comparison of both macrofossil and pollen assemblages with vegetation structure.

Studies by Dunwiddie (1987) and Wainman and Mathewes (1990) examined the extent to which conifer needles found in ponds from high-relief areas of Washington state and British Columbia represented the composition of Pacific Northwest forests. These studies also compared needle deposition with the pollen record. In a study that provides an excellent analog for early postglacial environments of the Northern

Hemisphere, Glaser (1981) observed transport of plant macrofossils across frozen tundra ponds in Alaska and their post-melt-off deposition.

Several studies have focused on higher energy environments not typically chosen for Late Glacial and Holocene paleoecological studies. Holyoak (1984) conducted research on a river catchment in Spitsbergen. Davis (1985) analyzed sediment from Upper Chesapeake Bay and conducted seed settling experiments to explain the assemblages found in sediment. Spicer and Wolfe (1987) examined conifer needles, leaflets, and seeds in a high-energy environment in mountainous northern California.

Most Southern Hemisphere surface sample macrofossil studies have been conducted in Tasmania and New Zealand, where the macrofossil assemblages are typically dominated by leaves. The flora of this region includes many broad-leaved, evergreen species whose leaves have thick cuticles and are less prone to rapid decomposition than those of most broad-leaved Northern Hemisphere species. Sediment is often seed poor, and the seeds tend to be small and difficult to identify. Hill and Gibson (1986) and Drake and Burrows (1980) studied the relationships between macrofossil assemblages and vegetation composition from lakes in Tasmania and New Zealand, respectively. McQueen (1969) tested whether macrofossils in a New Zealand lake represented multiple climate zones due to downhill transport in a high-relief environment.

Methods for Surface Sample Studies

Researchers typically select sediment sampling points along a predetermined transect or transects. A transect may be parallel to wind direction, along major lake axes, or perpendicular to shore. Samples may be taken at predetermined distances from shore, at select water depths, or within distinct vegetation zones. A grab sampler (Figure 1), surface corer (Figure 2), or dredge is generally used to collect the uppermost 2–4 cm of sediment, although sediment may be scooped by hand where the water is sufficiently shallow. Limiting collection to the uppermost 2–4 cm secures only the most recent few years of sediment, although studies have collected as much as the top 10 cm.

There are several quantitative methods for sampling aquatic vegetation: (1) surveys of the entire lake bottom using transects, releve plots, and divers; (2) quadrats in different vegetative units; (3) cover abundance in the immediate vicinity of sediment collection points, using a grapple to collect vegetation where water is insufficiently clear to identify species from the surface; and (4) distance to nearest mature individual of each plant species.

Lakeside vegetation is surveyed using standard methods, such as releves along a transect, cover abundance, or tree and shrub diameters. A researcher may use aerial surveys or record all species within a certain distance of the lakeshore. Understory plants, which typically have minimal representation within macrofossil assemblages, are recorded in releves along a transect.

Comparison of macrofossils with vegetation is complex and no standard methodology emerges from the research literature. Multivariate techniques may be used to compare complex data

Figure 1 A grab sampling device (shown here) is lowered in the open position. As it sinks into sediment, tension on the drop line is released, closing the sampler. A grab sampler has the advantages of being inexpensive and simple to use. However, the depth of sediment collected cannot be controlled and sediment is mixed to an unknown depth. By contrast, a Birge–Ekman dredge is triggered when the operator drops a messenger down the line, releasing the spring-closing jaws. By measuring the depth to the sediment surface, the operator can lower the dredge to the proper depth before triggering the jaws to ensure collection of the sediment–water interface.

Figure 2 A surface sediment corer is a highly accurate method of collecting surface sediment. The surface–water interface is collected in a clear, polycarbonate barrel. By removing the coring device from the top of the barrel, and pushing the bottom plug up from below, the sediment can be extruded in precise increments, ensuring collection of the uppermost sediment without mixing.

sets. Percentages of representation within the macrofossil assemblage and vegetation community may be compared. Typically, researchers report which species in the vegetation are represented in the macrofossil assemblages and to what degree

Figure 3 Sample graph comparing abundance of macrofossil type A to the presence of species A in the vegetational community. After Birks HH (1973) Modern macrofossil assemblages in lake sediment in Minnesota. In: Birks HJB and West RG (Eds.) *Quaternary Plant Ecology*, pp. 172–189. Oxford: Blackwell.

taxa are over- or underrepresented. Graphic presentation of these measurements enhances these comparisons (Birks, 1973; Figure 3). Researchers generally discuss which environments—aquatic, lakeside, or upland—are responsible for most macrofossil deposition. Studies also report the percentage of a macrofossil type found within a given distance of potential source plants.

Aquatic Seed Bank Studies

Aquatic seed bank studies provide important information about seed dispersal and sedimentation, although they are conducted for entirely different purposes than surface sediment macrofossil studies. Seed bank studies are generally conducted to determine what propagules are available for recolonization of a site or to ascertain what role the seed bank plays in maintaining established vegetation. In a seed bank study, sediment is collected and placed in a greenhouse under ‘ideal’ germination conditions. After a set amount of time, emerging seedlings are identified and counted.

Because of the different methodologies, seed bank studies are not directly comparable to surface sediment macrofossil studies, and caution must be exercised in using seed bank data for interpretation of macrofossil assemblages. Germination studies strive to measure ‘active’ components of the seed bank, those seeds or other propagules that retain the potential for growth. Only seedlings that survive to identifiable size are counted. Nonviable seeds, seed fragments, and vegetative fragments in the sediment are not represented. Germination studies are somewhat problematic for determining active components of the seed bank because greenhouse conditions may not precisely match conditions of the site from which the sediment was taken. Important germination cues such as light may vary, or seed burial depths may be incorrect. Potentially viable seed may be missed if specific germination requirements, such as chilling, or pregermination processing, such as passing through the gut of a bird, did not occur.

Published aquatic seed bank studies are uncommon. Keddy and Reznicek (1982) studied the relationship between existing vegetation and the seed bank of a coastal plain in Ontario. In a

study from a large, calcareous lake in Alberta, Haag (1983) grew seeds from sediment in a greenhouse and made interesting observations about seed production at different water depths. Kautsky (1990) examined seed and tuber banks from a bay of the Baltic Sea. Bonis and Lepart (1994) examined differences in the seed bank associated with depth in sediment for temporary saline marshes in France. Additionally, Bonis and Grillas (2002) wrote a useful review about charophyte propagule banks.

Macrofossil Production

Annual production of macrofossil type A, factor P_A of the previously discussed macrofossil:vegetation inference model, is very much dependent on the plant part in question. For example, plant parts that are intentionally shed on an annual basis (e.g., deciduous leaves, *Larix* needles, and bud scales), as well as reproductive parts such as seeds, staminate and pistillate strobili, cone scales, and oospores, can be expected to be found in sediment in significantly greater quantities than plant parts that are shed only occasionally or in small quantities (e.g., vegetative parts including twigs and evergreen leaves or needles). However, species with parts that break into identifiable fragments may be overrepresented in the fossil record depending on how fragments are counted (Holyoak, 1984).

P_A depends on reproductive and overwintering strategies of species A. Annual plants, which overwinter as seed, typically produce many times more seed per year than perennial species. Many obligate aquatic plant species successfully produce seed only under specific conditions. The primary reproductive strategy for these species is vegetative. They overwinter as tubers or dormant buds, which decay more readily than seed, reducing representation of these species in the macrofossil record. In a seed production experiment, Yeo (1966) found that the production of seeds by different aquatic species varied from zero to 2 million per plant. Production of tubers, turions, and dormant buds by species that rely on these reproductive methods varied from less than 100 to nearly 70 000. For low producers, such as *Nuphar*, just a few seeds may represent a large mass of plants, whereas for high producers, such as *Najas*, many seeds may in fact represent few plants.

To further complicate factor P_A , seed production may vary from year to year depending on environmental conditions. Some obligate aquatic species, for example, only produce seeds during dry growing seasons that leave the plants stranded above the water line. Bonis and Lepart (1994) found seed production differences of up to 600% within a single species. Production of charophyte oospores may differ from 4 to 70% from one year to the next (Bonis and Lepart, 1994; Bonis and Grillas, 2002).

Annual seed production may also vary among individuals of the same species in the same lake depending on site characteristics. Haag (1983) stated that seed production in some species decreases with increasing water depth because of reduced irradiance and a longer amount of time required to grow to the surface, where many aquatic species carry out pollination. Bonis and Grillas (2002) observed that decreasing water depth triggers sexual maturation of *Chara australis*, with

individuals remaining infertile in water over 54 cm deep; *Nitella sonderi* successfully set oospores at all water depths.

Taphonomy

Taphonomy, the study of processes by which fossils become incorporated into sediment, encompasses the other factors of the macrofossil:vegetation inference model: loss (L_A), dispersal distance (D_A), basin characteristics (b), and within-lake sample location (S).

Loss

Potential macrofossils are lost as a consequence of decomposition, predation, and seed germination, although germinated seeds may still leave behind identifiable fragments of seed coats. Long-term preservation is greatest for plant parts that are meant to be long-lasting, such as seeds with strong seed coats and evergreen leaves with thick cuticles. Although soft leaves decay more rapidly, even some of these may leave behind well-preserved parts, such as the spines of *Ceratophyllum* leaves. Spicer and Greer (1986) speculated that basin morphology can affect decomposition rate within sediment. A lake with a low surface area relative to its depth has less oxygen entering the water by means of diffusion across the water–air interface, creating a less aerobic environment and decreased decomposition.

Dispersal Distance

Dispersal distance of potential macrofossils from source plants is influenced by both species and basin/environment characteristics. Tiny seeds or parts, for example, are likely to be more widely dispersed than large ones. They may be carried a greater distance before settling and become resuspended and winnowed into deeper water as a consequence of seasonal overturn or wind-generated wave action. Dieffenbacher-Krall and Halteman (2000) found that, in general, potential macrofossils are deposited at water depths equal to or greater than the depth at which the source plants grow. Essentially, macrofossils are more likely to travel downhill, into deeper water, than they are to travel uphill. However, the study found exceptions to this generalization because wave action can push buoyant seeds back toward shore before they settle.

Macrofossil buoyancy has great significance with respect to dispersal distance, and a fair amount of data exist about seed buoyancy. In an article written in 1893, H. B. Guppy shared observations of seeds floating down the River Thames. Guppy pondered whether seed transportation by water might be a possible explanation for multicontinental distribution of some aquatic plant species. His curiosity led to greenhouse experiments in which he tested the seed buoyancy of 320 British plant species in both fresh and salt water (Guppy, 1906). Praeger (1913) studied seed buoyancy of 786 British plant species. Guppy's studies led him to conclude that long-distance transport of species via seawater was probably not a significant factor in circumboreal distribution of plant species, and he reverted to the usual suspect, waterfowl, as a more probable explanation. However, his and Praeger's studies still

constitute the greatest body of knowledge regarding seed buoyancy.

Guppy (1893, 1906) and Praeger (1913) found that the seeds of many species sink almost immediately, whereas others can remain buoyant for months in either fresh or salt water. Praeger reported that 44.3% of species tested had seeds that sunk within 1 minute, 12.6% of species had seeds that sunk within 1 day, and 30.2% had seeds that sunk within 1 week. The remainder were buoyant for longer periods of time. Guppy generalized that riverside and seaside species tended to have more buoyant seeds. He found that grasses possess little buoyancy, although air bubbles trapped in glumes may cause floating for a few days. *Scirpus* seeds sink rapidly, but *Carex* seeds may float for several months if they remain trapped within the buoyant utricle. It is important to note that Guppy used seeds in a condition nearly like that at the time of natural dispersal. Praeger thoroughly dried his seeds, which would increase their buoyancy. Thus, the results of the two researchers are sometimes in disagreement regarding the same species.

Davis (1985) tested the specific gravity and settling velocity of seeds of eight obligate aquatic species as part of his aforementioned surface sample study. He found that all seeds tested had specific gravities >1.0 and sank rapidly in distilled water, with the exception of *Potamogeton*, which floated. Davis speculated that seeds with slower settling velocities would tend to disperse more broadly; his surface sample analysis confirmed this hypothesis.

Little is known about buoyancy of macrofossils other than seeds. Hill and Gibson (1986) conducted floatation studies on leaves of 11 Tasmanian species. Most leaves floated for long periods of time, but 3 species had leaves that sank quickly. In their surface sediment samples, Hill and Gibson found that the more rapidly sinking leaves were deposited in nearshore sediments, whereas leaves of other species were dispersed more broadly.

Dispersal mechanisms also affect distance of dispersal from growing source plants. Kautsky (1990) found that *Potamogeton pectinatus* produced abundant quantities of seed, but the seeds were not found in sediment from immediately below the plants. The seeds remained attached to parent plants and drifted away with them as the plants senesced in autumn to be deposited on the shoreline in abundance. Wind-dispersed seeds, such as those of birch and conifers, are often found in great numbers in sediment samples from the center of lakes and in low numbers near shore. Seeds may also be transported away from parent plants by waterfowl.

Season of dispersal of potential macrofossils can greatly influence the distance of macrofossil settling from source plants. Macrofossils that disperse after snowfall, such as *Betula* seeds and pistillate bracts or *Larix* needles, may blow great distances over snow before coming to rest. Macrofossils blowing across a lake may become incorporated in the ice. The seeds melt down into the ice as a consequence of greater solar radiation absorption because of their dark color. Guppy (1893) observed many seeds being transported within ice and found that ice often damages seed coats. Although not affecting germination, seed coat damage causes the seeds to sink immediately after ice melt. Any macrofossils floating at the time of freeze-over become incorporated into ice and sink in place when the ice melts. Glaser (1981) found that macrofossils

may be sorted as they sweep across snow according to different aerodynamic properties.

Basin and Environmental Characteristics

Additional features of the local environment may affect dispersal distance, particularly the energy of the environment determined by the slope of the catchment basin and lake bottom. Shoreline vegetation impacts representation of terrestrial vegetation within the macrofossil record by filtering in-wash. The mode of entry into a basin by a macrofossil affects how far from shore the macrofossil settles into sediment. For example, macrofossils falling from overhanging branches tend to come to rest in nearshore sediment. Those carried by streams would have a distribution related to the energy dissipation pattern of the stream water. Sporadic events, including periods of high runoff, erosion, or local fires, can also change patterns of macrofossil distribution.

Sample Location within a Basin

Macrofossil deposition is not consistent across a basin. Assemblage composition varies with the sediment core location within a basin. More macrofossils are found in upwind sediment (Wainman and Mathewes, 1990), and nearshore sediment generally contains many more macrofossils than lake center sediment (Watts and Winter, 1966). Davis (1985) and Hill and Gibson (1986) also noted high spatial variability of macrofossil composition across a lake, with different samples providing very different pictures of the surrounding vegetation. Samples from different water depths reflect different vegetation zones within and around a lake, making macrofossils a useful proxy for past water level changes (Digerfeldt, 1986). Dieffenbacher-Krall and Halteman (2000) demonstrated that macrofossils from some species are deposited in a limited range of water depths, whereas others spread broadly across a lake.

Representation

All factors considered, how reliably can V_A be inferred from the macrofossil content of sediment? Certainly, a one-to-one relationship between macrofossils and vegetation community is not to be expected. Macrofossil abundance is not a direct measurement of plant abundance, and the absence of a macrofossil type does not confirm the absence of its associated plant in the local vegetation. However, Watts and Winter (1966) argued that quantitative analysis of macrofossils is valid. A predictable relationship may be made possible by evaluating individual macrofossil taphonomy and which species tend to be over-, under-, or not represented in the macrofossil record. Macrofossil presence within sediment is a definitive indicator of the local presence of particular plant species. Occasionally, one may find seeds of species not noted in a lake or surrounding vegetation, but these tend to be small plants easily overlooked in a vegetation survey, such as *Callitriche* or *Najas gracillima*. The results of surface sample studies provide strong evidence against long-distance transport as a possible confounding factor, finding very few incidences of macrofossil transport from substantial distances.

The macroscopic remains of aquatic and wetland species tend to originate near their sedimentation point. Greatrex (1983) estimated that 50–100% of aquatic and wetland macrofossils originated within 1 m of the sample sites. Zhao et al. (2006) determined that for some species, 100% of macrofossils derived from plants within 20 m of the sample sites. However, representation is inconsistent. In some cases, a macrofossil type is abundant where the plants are abundant. Often, however, a macrofossil type may be abundant with no potential source plants in the near vicinity (Birks, 1973; Dieffenbacher-Krall and Halteman, 2000; Zhao et al., 2006). Species abundance does not ensure abundance of its macrofossils in the sedimentary record. Greatrex (1983) found few *Carex* seeds despite the fact that the bulk of the sediment was composed of the vegetative remains of sedge. Rare species are unlikely to be represented in the macrofossil record, and some species simply do not appear to produce preservable macrofossils.

Surface sample studies confirm that macrofossil assemblages do not provide one-to-one representation of upland communities. Some woody genera, particularly *Betula*, *Alnus*, and *Larix*, are excessively prominent in macrofossil assemblages. Their abundance or near proximity to a sample site may better be determined by a combination of seed and vegetative remains rather than simply seed alone. Other genera, such as *Salix*, may not be observed in the seed record, but they may contribute other plant parts, such as scales, leaves, twigs, catkins, or stipules. Upland macrofossil assemblages may be swamped by abundant remains of obligate and facultative hydrophyte species. For these reasons, macrofossil data are usually presented as concentrations per unit of sediment rather than as percentages of macrofossil sum.

Macrofossil samples may contain remains of all the major forest species in a catchment (Spicer and Wolfe, 1987), or as few as 4 of 14 tree species and 10 of 16 shrub species may be represented (Wainman and Mathewes, 1990). Nonetheless, macrofossils provide a valuable means of characterizing local vegetation if relationships between macrofossil abundance and plant abundance are known. Dunwiddie (1987) concluded that needle assemblages in sediment from small ponds could provide estimates of past species composition in Pacific Northwest coniferous forest, although herbaceous plant representation was sporadic. He found that the macrofossil record represented 85% of tree species, but when herbaceous species were included, macrofossils represented only 22% of the total terrestrial flora. In a region of shifting ecosystem boundaries across Minnesota, Birks (1973) determined that macrofossil assemblages were specific to distinct ecotones.

Macrofossil and pollen analysis together greatly enhance accurate vegetational community reconstruction. Pollen assemblages often contain significant proportions of taxa that are not present in local vegetation (Dunwiddie, 1987), and they poorly reflect the aquatic species composition of a lake (Zhao et al., 2006). However, the long-distance transport issues that complicate pollen analysis are absent from macrofossil analysis. Some species, such as *Larix*, produce small quantities of pollen that is poorly represented in the pollen rain. However, *Larix* is generally abundant in the macrofossil record if the species was present in the local vegetation. Other plants, such as *Artemisia*, are rare in the macrofossil record but adequately

represented by pollen. Species living at ecological extremes of their geographic ranges or at treeline may not produce much pollen, but their presence is recorded by macrofossil remains. In these situations, the pollen assemblage may be misleadingly dominated by long-distance transport (Eide et al., 2005). Macrofossils can confirm the presence of some species, such as *Thuja plicata* in the Pacific Northwest, because macrofossils can often be identified to a finer taxonomic level than pollen. Birks (2003) and Birks and Birks (2000) cite multiple cases in which macrofossil analysis was essential for accurate interpretation of pollen records.

Conclusion

Plant macrofossils preserved in lake sediment do not provide a direct means of estimating proportions of species within local vegetation. Deposition of individual macrofossil taxa is affected by such factors as annual production of the macrofossil, annual loss of the macrofossil, dispersal distance from source plants, basin characteristics, and sample location within the lake. However, study of plant macrofossils in surface sediment samples, and comparison with vegetation surveys, provide the data necessary to make qualitative, if not quantitative, estimates of past vegetational community composition based on macrofossils. Such studies are the only means of discovering biases within macrofossil assemblages that result from taphonomic processes and individual species characteristics.

Introduction

Treelines and timberlines are eye-catching landscape and biological boundaries beyond which trees cannot grow for various reasons (Figures 1, 2, and 3). Temperature and precipitation thresholds are the most important factors in determining whether a site is treeless or not, but vegetation type, soil type, snow cover, topography, and wind can locally codetermine the limit of tree growth. For instance, low temperatures at Alpine or polar treeline significantly reduce production of plant tissues (Körner, 1999). Thus in comparison to other vegetational life-forms, trees are particularly affected by temperature deficits because of their strategy to accumulate large amounts of biomass to overgrow other plants. Moisture deficits determine the transition between forest and grassland communities. This treeline is often called 'lower treeline' or 'dry treeline' to distinguish it from 'Alpine', 'polar', or 'upper treeline'.

Most ecological studies prefer to differentiate between tree-line and timberline. Treeline (or tree limit) designates the limit of tree growth, and timberline (or forest line, forest limit) the limit of closed forests. In mountainous areas the transitional zone between these two vegetational boundaries is usually rather narrow under natural conditions (i.e., 100–200 m of vertical extent). Anthropogenic impact (e.g., pastoral activities or timber exploitation) tends to lower timberline more than treeline, causing an extension of the transitional zone (e.g., up to 300–400 m in the Alps). Polar and drought-caused timberline and treelines can be separated by very broad transition zones such as parklands with widely spaced trees (Arno and Hammerly, 1993).

The spatial position of treeline depends on the definition of 'tree'. The most common criterion to define 'tree' at treeline is a minimum height between 2 and 8 m, and this criterion is sometimes used to separate timberline from treeline (e.g., 8 m versus 2 m of tree height, Tinner and Theurillat, 2003). Above treeline, tree species may grow as low, prostrate, or stunted individuals (<2 m, Figures 4 and 5). This zone is often referred to as the krummholz zone, and its upper limit as krummholz limit or tree-species limit. In the zone between timberline and the krummholz limit, total biomass drops dramatically (e.g., at the boreal forest limit from ca. 20 kg m⁻² to 0.6 kg m⁻², Strasburger, 1991) since tall trees are gradually substituted by shorter shrubs and herbs. Net primary productivity also declines, though to a less extent (e.g., in the Alps from ca. 1000 g/(m²·yr) to <200 g/(m²·yr), Ellenberg, 1996). Vegetational changes at treeline strongly influence many ecosystem elements and processes (e.g., animal life, soil formation, water balance, local climate, energy, and nutrient fluxes) and are, therefore, an exceptionally attractive subject of ecological and paleoecological research.

The main aim of paleoenvironmental treeline studies is to reconstruct past treeline positions and compositions. The

significance of such reconstructions lies mainly in two factors: (i) the paleoclimatic approach uses the climatic sensitivity of treelines to quantify past climatic changes at decadal to millennial scales. Due to the local to regional spatial resolution such studies provide valuable information about climatic changes at mountainous or polar sites; and (ii) the paleoecological approach uses independent environmental proxies (e.g., oxygen isotopes as climatic proxy) to provide insights into biosphere responses to rapid and/or extreme environmental changes.

Reconstructing Treelines by Using Macrofossils

Treeline changes can be reconstructed by consulting natural environmental archives such as lake or mire deposits. In such deposits, pollen is usually ubiquitous and, therefore, easy to be analyzed and quantified. However, because pollen is easily transported by winds over long distances and great elevation differences, pollen records at treeline have rather low spatial resolution and are, therefore, difficult to interpret. Macrofossil and megafossil analyses are considered to be more reliable tools for reconstructing treelines, since they have higher spatial resolution (meters to decameters) than pollen studies (decameters to kilometers; Birks, 2001). Megafossil and macrofossil records have also higher taxonomic resolution. If compared with megafossil studies, macrofossil studies have two advantages: (i) due to their small sizes (0.1 mm to cm-sized) macrofossils are deposited in stratigraphic order and can, therefore, provide complete Holocene and/or Glacial sequences with high-temporal resolution from single sites; and (ii) in contrast to megafossils, macrofossil numbers are sometimes high enough to be evaluated quantitatively, in a manner similar to that for pollen, diatoms, or chironomids. However, megafossils have the advantage of higher spatial resolutions, since they are often found *in situ* where they were growing. In addition, logs may be used for temporally precise dendroecological or dendroclimatic studies (e.g. Nicolussi et al., 2005).

To gain treeline-inferred temperature reconstructions it is assumed that the present occurrence of trees at treeline is in equilibrium with local climate of recent decades. After having determined the past spatial position of treeline by macrofossil analysis, past treeline fluctuations (m) can be converted to (summer) temperature changes (°C) by using today's lapse rates (under the assumption of, for example, Holocene stability). In regions affected by strong human impact (e.g., the Alps) single trees in remote areas may still indicate the potential altitudinal limit of forest and tree growth (Figure 4). A second assumption is often made when interpreting pollen and macrofossil records at treeline. Changing values of tree species in pollen or macrofossil records are usually considered to reflect tree-population dynamics rather than productivity changes of

Figure 1 Lower and upper timberlines in the continental climate of Idaho, USA. Sagebrush (*Artemisia* steppe) in foreground. Tree growth is prevented by lack of moisture on the lower slopes. Photograph by HH Birks.

Figure 2 Upper natural timberline in the Rocky Mountain National Park (CO, USA, established 1915). Timberline is formed by *Abies lasiocarpa*, *Picea engelmannii*, and *Pinus flexilis*. The transitional zone (ecotone) between sub-Alpine forests and Alpine meadows is narrow and forests rather closed up to treeline. Photograph by W Tinner.

Figure 3 Timberline in the Swiss Central Alps (Valais region) is located at about 2000–2200 m and if compared with the natural position it is lowered by about 200–400 m by anthropogenic activities. It is formed by *Picea abies* (up to ca. 2100 m), *Pinus cembra*, and *Larix decidua* trees. The lower parts of the forests are disrupted for economic purposes. In the foreground, the study site Gouillé Rion (2343 m a.s.l.) which is situated at today's treeline. Photograph by W Tinner.

Figure 4 Highest occurrences of *Pinus cembra* trees near the site Gouillé Rion, Central Swiss Alps. The size of the trees is decreasing with increasing altitude (ca. 2320–2400 m a.s.l. (above sea level) in the picture). Uppermost individuals at about 2380 m a.s.l. reach a size of ca. 0.5 m. Trees at these altitudes are restricted to rocky slopes which are not easily accessible. Photograph by W Tinner.

Figure 5 Highest *Pinus cembra* individual near Gouillé Rion (Swiss Alps) at 2415 m a.s.l. The *Pinus cembra* krummholz shows winter damage by desiccation which is identifiable by the orange–brown color of dead shoots. During winter the low portions of the shrub were encased in snow packs and thus protected from winter drought. In the background single trees and tree groups of Swiss stone pine at 2350–2300 m a.s.l. (= treeline). Photograph by W Tinner.

the individuals alone such as higher pollen or plant-organ production in response to warmer climate. For instance, reduced macrofossil concentrations of tree species are conventionally interpreted as the consequence of a local decline in treeline elevation.

Macrofossil data are usually presented as concentration data, i.e., as macrofossil numbers or areas (e.g., mm²) per volume of sediment (e.g., 50 cm³, Birks, 2001). The reason for such a procedure is that the numbers found in the sediments are generally too low to allow reliable estimates of accumulation rates or calculation of percentages. However, in contrast to percentage values, concentration values presuppose uniform sedimentation rates. Another constraint of concentration values is that, in contrast to accumulation rates and percentages, they cannot be directly linked to modern vegetational data or observations, although the establishment of such a link

is compelling for a correct interpretation of any kind of paleoecological data. In treeline studies one of the most important questions is whether a site was below, at, or above treeline. Due to the above-mentioned restrictions, it is not easy to address this question in detail by using macrofossil concentration values alone. Macrofossil percentages may help to address this issue where numbers are high enough and provided that the range of values does not differ greatly among the taxa (Briks, 2001). Different studies have shown that sums should reach 45–50 to produce reliable percentage results (Hofmann, 1986; Heiri and Lotter, 2001). In the best case, macrofossil sums should be dominated by only one kind of macrofossil type (e.g., needles or leaves) to reduce the range of values. A recent treeline study from the Alps (Kaltenrieder et al. 2005, Tinner and Kaltenrieder 2005) illustrates this approach (Figure 6). In a first step, macrofossil-concentration values from two independently radiocarbon-dated cores (10 m apart in a small lake) were compared to assess whether the macrofossil results can be reproduced temporally and spatially. For this purpose the temporal resolution of the counts of core GR6/7 was lowered by always amalgamating six adjacent samples. Even minor fluctuations in macrofossil numbers, such as the different peaks of *Larix decidua* needles, occurred in both stratigraphies, indicating that low macrofossil counts and local tafonomic processes did not significantly affect the spatial and temporal reproducibility of the data. In a second step, macrofossils (e.g., needles, leaves, or fruits) of taxa that could be unambiguously attributed to trees (indicating forest), shrubs (shrublands), or creeping shrubs and upland herbs (Alpine meadows, debris vegetation, or snowbeds) were considered for percentage calculation, whereas wood fragments, twigs, charcoal, bark, aquatic plants, and Cyperaceae were excluded

from the macrofossil sum (Tinner and Theurillat, 2003). Since macrofossils are not transported very far from their point of origin, the subsums indicating growth of forests, shrublands, or Alpine meadows (Figure 6) provide valuable information about the past dominant vegetational types at this site. According to the percentage data the site was densely forested from about 10 000–4500 calibrated years before present (cal yr BP; sums of trees usually between 90% and 100%). Alpine meadows were predominant before 11 500 cal yr BP and admixed with forests prior to 11 000 cal yr BP, whereas a special vegetation type dominated by shrublands and meadows (treeline ecotone) became established after 4500 cal yr BP. This enlargement of the treeline ecotone was primarily a result of human activity (Tinner and Theurillat, 2003).

Late-Glacial Treeline Dynamics

In the temperate biomes of the Northern Hemisphere, (dense) forests and thus treelines were established during the early Late-Glacial, ca. 18 000–14 500 cal yr ago. Only the southern regions of Europe were forested during this early period of the Late-Glacial, and macrofossil records show that treeline depressions there reached at least 1000–1500 m in comparison with today. For instance, radiocarbon-dated macrofossil records unambiguously document rather closed *Pinus cembra* treeline stands at 400–500 m in the southern Alps ca. 16 000–14 500 cal yr ago (e.g., site Balladrum, near Locarno; Hofstetter et al., 2006 in press). Summer temperatures increased abruptly after 14 500 cal yr BP (Heiri and Millet, 2005), and treelines in southern Europe subsequently reached higher positions, although they were still about 600 m lower

Figure 6 Comparison of macrofossil records from different cores with independent chronologies from the treeline pond Gouillé Rion (2,343 m a.s.l., Swiss Alps): (a) Macrofossil concentrations of core GR2. The age–depth model used for the chronology of GR2 relies on 14 mass spectrometry ^{14}C -measurements on identified terrestrial plant macrofossils. (b) Macrofossil concentrations of core GR6/7, always six adjacent samples of 0.5 cm were amalgamated to reach temporal resolutions comparable with GR2. Cores GR2 and GR6/GR7 are 10 m apart. The age–depth model used for the chronology of GR6/7 relies on 12 mass spectrometry ^{14}C -measurements on identified terrestrial plant macrofossils. (c) Core GR6/7, same data as (b) but with sixfold higher resolution. (d) Macrofossil percentages for core GR6/7, same resolution as (c). For details on macrofossil percentage calculations see Tinner and Kaltenrieder (2005).

than they are today. Similarly, macrofossil studies document that after having been established at about 15 000–14 500 years ago, treelines in and north of the Alps were depressed by about 600–800 m during the period 14 500–11 500 cal yr ago (Tobolski and Ammann, 2000, Gobet et al., 2005).

Strong treeline depressions during the Late Glacial were also characteristic for Northern America. Macrofossil studies document that treeline was lowered by at least 600 m during the period 17 000–13 500 cal yr BP in the Yellowstone and Grand Teton National Park areas (Whitlock, 1993). After 13 500 cal yr BP treelines moved upwards, but today's forest limits were reached only after 11 500 cal yr BP at the beginning of the Holocene. These results from the Northern Rocky Mountains are corroborated by pollen studies in the Southern Rocky Mountains, suggesting that before 13 000 cal yr BP treeline was lowered by about 300–700 m (Fall, 1997). Detailed macrofossil studies covering the Late-Glacial period, however, are still very rare. Considering the high climatic variability of this period, new macrofossil series with a high chronological resolution and precision would allow a better assessment of local impacts of strong climatic change on treeline vegetation.

Holocene Treeline Dynamics

At the beginning of the Holocene treelines moved rapidly upwards, as shown by the analysis of macrofossils from lake and mire deposits along altitudinal transects. In the Alps, the timberline ascended 800 m in 200–300 years (11 550–11 350 cal yr BP, see Figure 6 for expansion of trees at today's treeline at about 11 350–11 250 cal yr BP; Tinner and Kaltenrieder, 2005). These rapid vegetational changes were caused by abrupt climate warming of about 4–6 °C at around 11 550–11 350 cal yr BP. During the Holocene, the position of timberline and treeline in the Alps fluctuated within a band of 100–180 m, and treeline was at its uppermost position (ca. 180 m higher than today) during the period 10 000–6000 cal yr BP (e.g. Tinner and Theurillat, 2003). A virtual transect from the central Alps (Figure 7) starting at about 300 m below (2017 m) and ending at about 200–250 m above the today's tree limit (2557 m) illustrates how sharply and unambiguously past forest-Alpine transitions can be traced by macrofossil analysis. Before the onset of large-scale agricultural activities at ca. 2200 BC (Bronze Age), forests were rather closed up to the tree limit at ca. 2400 m (sites Simplon and Goullé Rion in Figure 7). Above the forest limit, the treeline ecotone encompassed about 100–150 m and was characterized by the mixed occurrence of tree, shrub, dwarf-shrub, and herbaceous species (site Goullé Loéré). Natural meadows dominated by creeping shrubs and herbaceous species formed the alpine belt above the treeline ecotone (site Lengi Egga, Figure 7). After 6000–5000 cal yr BP timberline and treeline progressively declined by about 180 m and 300–400 m, respectively. The regression of densely forested areas (timberline) in the Alps during the past 5000 years was primarily caused by human impact, whereas the course of treeline was primarily driven by climatic change (Tinner and Theurillat, 2003). Macrofossil studies suggest that severe diebacks of treeline vegetation occurred during cold-humid periods (CE-1–CE-8, see Figure 8) such as

the 8200 cal BP event. During the early and mid-Holocene treeline oscillated by about ± 50 –100 m. A severe treeline decline lasted from 8400 to 7500 cal yr BP (CE-3), with two minima at 8000 and 7600 cal yr BP. Assuming constant lapse rates of 0.7 °C/100 m it is possible to estimate the Holocene temperature oscillations in the Alps as 0.8–1.2 °C between 10 500 and 4000 cal yr BP, when (summer) temperatures were about 0.8–1.2 °C higher than today. After 4000 cal yr BP summer temperature successively declined to values comparable to the average values of the twentieth century.

At the beginning of the Holocene at ca. 11 550 cal yr BP most areas of Scandinavia were still glaciated. Coastal areas, however, were partially ice-free and thus provide evidence for the earliest afforestation. Macrofossil records show that treeline reached the coast of southwestern Norway (Kråkenes, 62° N) at ca. 10 900 cal yr BP, about 650 years after the beginning of the Holocene (Birks, 2003). Megafossil finds suggest that at about the same time (ca. 11 000 cal yr BP) the tree limit in interior Scandinavia (63° N) had abruptly reached very high positions 100–300 m (uncorrected for glacioisostatic land upheaval) above the modern tree limit (formed by *Betula pubescens* at ca. 800–1000 m a.s.l.), briefly or immediately after the deglaciation (e.g. Kullman, 1995; Bergman et al. 2005). This would imply an almost synchronous expansion of trees over about 1000–1200 altitudinal meters and over distances of hundreds of kilometers. However, recent macrofossil studies along altitudinal transects (Bergman et al. 2005; Eide et al., 2006) suggest that these very early megafossil finds may represent scattered individuals in extremely favorable microclimatic settings and that the regional expansion of forests and thus the establishment of continuous treelines occurred later, at around 9500–9000 cal yr BP (Figure 9). The general subsequent course of Holocene treeline fluctuations in Scandinavia is similar to that reconstructed for the Alpine sites. Megafossil, macrofossil, and pollen studies suggest that treeline was at its uppermost limit between 9500–9000 and 6500–6000 cal yr BP in Norway and Sweden, about 200–400 m above the present treeline position. At some study sites, treeline declined temporarily between 8300 and 8000 cal yr BP (e.g. Dahl and Nesje, 1996; Barnekow, 1999, Barnett et al. 2001). Use of today's lapse rates implies that during the period of highest treeline positions summer temperatures were 1.3–2.0 °C higher than today. A consistent pattern emerges from Asian macrofossil studies (e.g. Kremenetski et al., 1998; MacDonald et al., 2000). Forests across northern Russia developed at the onset of the Holocene at 11 500 cal yr BP. Maximum polar treeline positions were reached at 10 000–5000 cal yr BP, probably in response to summer temperatures 2.5–7.0 °C warmer than modern.

Megafossil and macrofossil records from North America (e.g., Yellowstone and Grand Teton National Park: Whitlock, 1993; San Juan Mountains: Carrara et al., 1991; and New Hampshire White Mountains: Miller and Spear, 1999) suggest that today's treeline positions were reached at the end of the Late Glacial and the beginning of the Holocene at about 12 500–11 000 cal yr BP in response to climatic warming and/or more moisture availability. If compared with Eurasia, today's treeline positions were reached about 1000 years earlier at some of the North American sites. This early development may have resulted from warmer conditions during, for

Figure 7 Virtual macrofossil and vegetational transect along an altitudinal gradient in the Swiss Central Alps (Valais region). The macrofossil data are in percentages. Modified from [Tinner and Theurillat \(2003\)](#), with permission. The tree macrofossil sum shows the decreasing relevance of trees (e.g., *Larix decidua*, *Pinus cembra*, and *Betula*) with increasing altitude. In the treeline ecotone shrubs are important. Above the treeline ecotone herbs and creeping shrubs are predominant (Alpine meadows, snow-bed, and debris vegetation). The vegetational transect shows a reconstruction of treeline vegetation for the period 10,000–5,000 cal yr BP, when forests were dominated by *Pinus cembra* and *Larix decidua*. Today Simplon and Gouillé Rion are located in the treeline ecotone, with a mixture of shrub (e.g., *Calluna vulgaris* and *Juniperus nana*), tree and herb species, whereas Gouillé Loéré and Lengi Egga are situated in the Alpine belt where herbs (e.g., *Carex curvula*) and creeping shrubs (e.g., *Salix herbacea*) are predominant.

example, the Younger Dryas (see Late-Glacial treeline dynamics above). Unfortunately, there are only a few North American studies available, and in addition they have rather low temporal resolution and precision. In combination with the radiocarbon plateau at the Late-Glacial/Holocene transition (e.g., 10 500 ^{14}C yr BP = 12 570 cal yr BP; 10 100 ^{14}C yr BP = 11 660 cal yr BP) this may have affected the establishment of a reliable chronology. However, in western North America radiocarbon-dated megafossils and macrofossils that have been preserved in alpine environments provide direct and unequivocal evidence for past high stands of Alpine timberline (e.g. [Carrara et al., 1991](#); [Fall, 1997](#); [Reasoner et al., 2001](#); [Figure 10](#)). The recovery of wood and macrofossils ranging in age from ca. 10 000 to 5000 cal yr BP from sites situated 100–270 m above present treeline clearly indicates that sub-Alpine forests reached at least this elevation during the early and mid-Holocene and suggests that mean (summer) temperatures were 1–2 °C warmer than today. Macrofossil records from across southwestern Canada ([Reasoner et al., 2001](#)) indicate two clear periods of higher-than present treeline during

the Holocene: an early phase from ca. 11 000–10 000 to ca. 8,200 cal yr BP and a later phase between 7300 and 5700 cal yr BP. These data are in general agreement with the European records, suggesting that the 8.2 event may have impacted treelines on a northern hemispherical scale. Moreover, dendrochronological analyses of living trees near alpine treeline and dead snags *in situ* in North America document abrupt synchronous terminations of tree-ring records in response to Holocene climatic oscillations such as the Little Ice Age (e.g. [Luckman, 1994](#)).

It is clear that the position and composition of the timberline ecotone has been sensitive to Late-Glacial and Holocene climate change. The millennial-scale trends generally reflect gradual decline in northern hemisphere insolation from approximately 11% higher-than-present at the end of the Late Glacial and in the early Holocene. Superimposed on this long-term trend are higher-frequency fluctuations related to changes in oceanic circulation, volcanic activity, and solar irradiance or a combination of these factors. Most of these factors influenced climate at continental to global scales, but

Figure 8 Comparison between (a) macrofossil concentrations, (b) pollen percentages, and (c) simulation results for Gouillé Rion (2,343 m a.s.l., Central Swiss Alps). No correction factors were applied to the pollen data. The order of the species in the legend corresponds to the order in which they are plotted in the figures. Modified from Heiri et al. (2006), with permission. Macrofossil and pollen data from Wick and Tinner (1997). Vegetation-independent Holocene temperature scenario for the Swiss Alps from Heiri et al. (2004). Central European cold phases (CE) according to Haas et al. (1998).

currently it is unclear whether they generated synchronous oscillations of treelines over such wide ranges. The similarity of the general Holocene treeline trends in North America and Europe suggests at least the possibility of such intercontinental linkages, though new high-resolution records are necessary to resolve this issue.

Fossil Evidence and Models: Linking the Past to the Future

It is clear that anthropogenic climate forcing over the next 100 years is likely to rival or exceed the warmest conditions of the Holocene. Concerns about global warming involve

Figure 9 Comparison between records of macrofossils, pollen influx, and radiocarbon-dated finds of subfossil wood remains (megafossils) in the Scandes Mountains, west-central Sweden from Bergman et al. (2005), with permission. The macrofossil and pollen data are from Lake Stentjärn (987 m asl). The original megafossil data were presented in different studies (e.g., Kullman, 1995). The local limit of *Pinus sylvestris* at the end of the nineteenth century is used as reference level. (●) *Pinus sylvestris*, (○) *Betula*, (x) *Alnus incana*. The vertical lines labeled A and B represent upper limits of *Alnus incana* and *Betula pubescens*, respectively.

adjustments, collapses, migrations, or extinctions of boreal and Alpine life. A promising way to assess the environmental consequences of future global change is to use experimental and long-term monitoring data to establish quantitative models and to check the model-based results by paleoenvironmental records. For this purpose, Holocene treeline dynamics along an elevational transect in the Central Alps were simulated by using the forest succession model FORCLIM (Heiri et al., 2006; Figure 8). An independent (chironomid-inferred) temperature reconstruction from the northern Alps (Heiri et al., 2004) was used to drive the model. The simulation results, yielding treeline fluctuations of about ± 100 m above the today's treeline (2350–2400 m, data of altitudinal fluctuations not shown, see Heiri et al., 2006), show a good agreement with pollen and macrofossil data for the period between 11 500 and 4500 cal yr BP (see Holocene treeline dynamics above). Moreover, the timing of treeline lowerings as suggested by the model corresponds to decreases of pollen and macrofossil values of the predominant tree timberline species *Pinus cembra* (e.g., during CE-1–CE-6, Figure 8). These results corroborate the interpretation of most paleoecologists that decadal-to-centennial-scale Holocene fluctuations of pollen and macrofossils reflect treeline shifts rather than productivity changes alone. After 4500 cal yr BP the macrofossil data suggest a distinct lowering of the treeline (Figures 7 and 8), while the model projects the presence of forests up to an altitude of 2400 m a.s.l. This discrepancy between paleobotanical data and simulation is explained by human impact on treeline, a factor that is not considered in the model. In fact, concomitant with the macrofossil-inferred lowering of treeline, pollen types indicative of human impact (e.g., *Plantago alpina*, *Cerealia* from fields in the lowlands) increased markedly at this site (Tinner et al., 1996). Other discrepancies such as the presence of *Picea abies* in the model and its absence in the macrofossil data are explained by precipitation changes that are not considered in the model because such realistic reconstructions are still lacking (e.g., less moisture availability during the early Holocene impeding the expansion of *Picea*). The validation of the model with paleobotanical data was thus successful for the natural or quasinalural period before 4500 cal yr BP, when the treeline position was mainly controlled by climate. This is a first important step towards applying forest-succession models for assessing future vegetation dynamics at treeline.

Independent from their function to validate quantitative models, paleotree line records provide valuable insights in long-term environmental processes that are not easily recognizable, since they exceed the human life span. If the treeline reconstructions are compared with independent proxies of environmental change it is possible to reconstruct past response dynamics. Surprisingly, relatively few studies have addressed past responses of ecosystems such as treeline communities to, for example, climatic change. One reason for avoiding this topic in paleoecology is that accurate studies are extremely labor-intensive and thus require strong efforts to reach very high temporal resolutions (<10–20 yr/sample) and precisions. To assess how treelines could respond to global change new high-resolution studies emphasizing macrofossil analysis are urgently needed. The importance is underscored by recent studies suggesting that polar and Alpine treelines are probably already responding to global warming over recent decades (Kullman, 2002; Holtmeier and Broll, 2005).

Acknowledgments

I am grateful to Hilary Birks, Mel Reasoner, and Petra Kaltenrieder for useful suggestions on the manuscript and for providing data or pictures.

Introduction

Environmental archaeology concerns the study of vegetation (flora) and animals (fauna), which lived in association with people of the past, and the way in which humans interacted with these other living organisms (Wilkinson and Stevens, 2003). The study of once-living organisms in archaeology is termed bioarchaeology and forms part of the 'archaeological sciences' (Figure 1).

Within these, archaeobotany or paleoethnobotany is the study of ancient plant remains (as proxy-data) preserved on, or in association with, archaeological sites ('on-site data'; Kreuz, 1995; article of Barker in Albarella, 2001; Jacomet and Kreuz, 1999; Pearsall, 2000). This is a contrast to paleoenvironmental approaches because plant remains from archaeological sites are 'ecofacts' and there as a result of human action. As paleoeconomic studies are carried out on archaeological material that happens to be biological, the approach is a combination of archaeology and the biological sciences. It is for this reason that developments in archaeological theory have much greater relevance to paleoeconomic studies (Wilkinson and Stevens, 2003). Today therefore, environmental archaeologists are both archaeologists and natural scientists and should have trained in both areas.

Environmental archaeology is mainly interested in the activities carried out by past populations (Tables 1 and 2). It usually covers the time period in which modern humans interacted somehow with their environment (ca. the last 40 000 years). Here again, the period in which sedentarism arose – at around 10 000 calendar years (cal yr) ago in different parts of the world (Diamond, 2002) – is by far the best represented. This covers mainly the present interglacial period, the Holocene (Table 3).

The timescale used in this article is that which is most familiar to archaeologists, namely calendar years AD resp. BC. Dating is partly based on calibrated radiocarbon dating and partly on dendrochronology.

Methodological Basics

Types of Remains

The most important macroremains (average size >0.1–0.2 mm) from archaeological sediments are seeds, fruits, parts of infructescences (like cereal chaff; Figures 2 and 3), and wood. In certain cases they are found as imprints (Figure 4) or in 'products' such as bread or coprolites. Theoretically every part of a plant can be found as an ecofact. Although in the following we deal only with macroremains, it should be emphasized that also microremains (pollen, fungal spores, etc.) in archaeological structures are ecofacts and their spectra and amounts are to a high degree a result of

human action. For more details see Dimbleby (1985); Pearsall (2000); and Jacomet and Kreuz (1999). (see also Table 6).

Taphonomy

Archaeologists use the term taphonomy to explain the processes that lead to the preservation (often fossilization) of biological remains (Schiffer, 1987; Jacomet and Kreuz, 1999, figure 4.8, p. 79). There are two aspects to consider when evaluating archaeological data: structural and depositional evidence. Structures are what people construct (buildings, fences, wells, ditches, and pits). Deposits result either from deliberate human action, as for example storage of grains in pits or in disposing of rubbish, or they may result from indirect processes that are not intentional by humans, such as silting of ditches. Deposits will contain the vast majority of biological remains that are studied by environmental archaeologists. These remains belong to different categories depending on how they reached the site (Figure 5). Negative features (like pits) commonly become infilled following their abandonment (Figures 6 and 7).

The processes by which a site is buried will have a major impact on how well archaeological and biological remains survive. Generally, material will be best preserved when burial is rapid and the energy levels by which the burying medium is deposited are low. A good example is the Roman town of Pompeii which was very rapidly buried by the eruption of the volcano Vesuvius in AD 79, but we can find rapid burial also in Neolithic lake-shore and mire settlements in the lowlands surrounding the Alps (Figure 8). The converse of the rapidity/energy correlation is also true: slow burial and high energies make for poor preservation and biological preservation is, therefore, likely to be minimal (Schiffer, 1987).

Preservation

Preservation of plant material from excavations may be different from that in natural sediments (Figure 9 and Table 4). Charring is the most common of all archaeobotanical preservation types. It preserves plant material after it has been subjected to burning (or smoldering), transforming the plant parts (particularly the dense or woody parts) from a carbon-based compound to almost pure carbon (Figure 10; Jacomet and Kreuz, 1999; Wilkinson and Stevens, 2003). Potentially charred material can be recovered from any archaeological site where fires have burnt or to which fire waste has been brought (so most commonly in settlement sites, but also, for example, in incineration graves). The most common type of charred plant remains is wood charcoal because wood is usually used to fuel fires. In addition, the most frequent charred remains are those resulting from the processing of food plants (like cereal grains, chaff, and the weed seeds that were accidentally harvested). Charred

Table 2 The archaeological and supporting data which relate to each stage of food-provision. The table shows the potential abundance of the evidence which can be applied to the study of ancient food systems

<i>Food provision stage</i>	<i>Types of material remains</i>	<i>Supporting data</i>
Procurement	– plant remains – animal remains – resource procurement tools – human remains	– ethnography – experimental replication – biology
Storage	– silos – bins – storage vessels	– ethnography
Preparation	– hearths, ovens – other preparation installations – tools e.g. mortars, querns, flint & metal blades – vessels: pottery, metal, basketry – house layouts – food residues and remains – butchery marks	– ethnography – experimental replication – biology
Consumption	– vessels – house layouts – gut contents: known individual, short time – coprolites: unknown individual(s), short time – cess: known/unknown individual/group, variable time span – human remains: individuals, variable span	– ethnography – experimental replication (for digestive processes) – biology

(Continued)

Table 2 (Continued)

Food provision stage	Types of material remains	Supporting data
Disposal	Remains disposed of: – vessels – preparation by-products – leftovers Condition of remains – e.g. whole vs. cracked bones Disposal patterns within/around settlement	– ethnography

Table 3 Chronology table: The last ca. 10 000 years are covered by most of the archaeobotanical investigations

Compiled by S. Jacomet © IPNA Basel University, based partly on Bogucki P and Crabtree PJ (eds.) 2004. *Ancient Europe 8000 B.C. – A.D. 1000. Encyclopedia of the barbarian world, Vol. 1, The Mesolithic to the Copper Age (c. 8000–2000 B.C.)*.

Figure 2 (a) Taking samples on an excavation (Biesheim-Kunheim, Alsace, France, Roman period, mainly 1st/2nd century AD): visible is a pit lined with wooden planks and filled with rubbish and cess, the preservation is waterlogged in the deeper areas of the pit (brownish sediments with high organic content). In the foreground, the wooden planks are sampled, in the background a white bucket is visible in which the soil samples are filled. (b–d) Examples of subfossil macroremains from the same site. (b) seed of *Vaccaria pyramidata*. (c) seed of *Agrostemma githago*. Both are weeds of winter-sown crops. As far as we know, *Vaccaria* was introduced by the Romans to the northern parts of Europe, whereas *Agrostemma* reached this region in late Neolithic times. (d) olive-stone (*Olea europaea*). Olives were imported from the Mediterranean in Roman times. Photographs made by S. Jacomet (a) and G. Haldimann (b, c and d), © IPNA Basel University.

plant parts belong to different classes, according to the nature of their deposition (Table 5). Identifying which type is present on a site is a prerequisite in interpreting charred plant remains.

Mineralization usually occurs when minerals carried in solution are deposited around plant cell surfaces or within inner voids, effectively encasing the plant structure (Wilkinson and Stevens, 2003; Jacomet and Kreuz, 1999). The most common form of mineralization on archaeological sites is as a result of calcium phosphate precipitated from cess. Therefore, mineralized remains are commonly found in middens, cesspits, latrines, sewerage systems, and comparable conditions and help to reconstruct what people were eating (Figure 11). However, mineralization by other materials such as the metals bronze and iron have also been recorded. Note that plant remains are differentially preserved by mineralization, and some remains are not preserved at all. Those of edible species whose seeds and pips are often ingested and so associated with cess are overrepresented; examples are seeds of figs, grapes, blackberries/raspberries, *Apiaceae* (like fennel or coriander), and *Rosaceae* (like plum and apple pips). However, cereal grains are rarely preserved by this mechanism.

Waterlogged plant remains are recovered from archaeological features that contained water when they were dug, such as wells, cesspits, sewers, moats, and ditches (Figure 7). But also whole layers may be preserved under the water table, like in the case of the circumalpine Neolithic and Bronze Age lake dwellings (Figure 8). Waterlogging has the potential to preserve a much greater range of plant material than where plant material

is preserved ‘only’ by charring or mineralization (Figure 9 and Table 4).

Plant remains preserved by desiccation are commonly found in arid situations like deserts, but also in totally dry caves or rock shelters or inside houses (e.g., in false ceilings; Jacomet and Kreuz, 1999). Desiccation occurs when moisture levels are too low for the organisms responsible for organic decomposition to survive. Desiccation can also preserve remains that are not otherwise found in the archaeobotanical record, including whole fruits, flowers, leaves, vegetables (e.g., onion skins in graves of Pharaonic Egypt).

In frozen environments, low temperatures render most decomposing organisms inactive, therefore well-preserved plant remains are common finds. Probably the most famous such find is the Iceman from the Italian/Austrian border near the Similaun Glacier in a height of over 3200 m above sea level (Dickson et al., 2003). As with other examples of burials, the information from frozen bodies is often personal and concerns the last meal of the deceased, his last journey, the use of plant material for clothing, and artifacts (Figure 12). However, the Iceman is preserved with his every-day equipment and clothing, thus shedding light on his lifestyle, in contrast to graves that are specially prepared ‘death assemblages’.

Types of Plant Assemblages, Sampling

Most of the assemblages found on archaeological sites are death assemblages (thanatocoenoses), containing materials from

Figure 3 Cereal remain types, the example shows the component parts of hulled wheat. Reproduced with permission from [Wilkinson and Stevens 2003](#), figure 62, p. 159.

different places around a site and altered by human (or animal) action. Only rarely paleobiocoenoses may be preserved, for example an uncleaned harvest in a burnt layer just after harvesting.

Until it is understood how an archaeological deposit formed, and how it was modified since its original placement, none of the paleoecological interpretation models can be used. Before these ideas can be applied we have to be able to assess the effects of processes operating during deposition and following burial, on the preservation, and integrity of archaeobiological assemblages (i.e., the likelihood of all material at a particular level having been deposited at the same time).

Knowledge of the formation of archaeological plant assemblages is especially important at the stage of sampling. Plant macroremains on excavations are recovered from bulk samples of often many liters of volume, depending on the find densities of the structures excavated ([Figure 2a](#); for more details see [Jacomet and Kreuz, 1999](#); and [Wilkinson and Stevens, 2003](#)). Samples should not be taken where their purpose is not understood or contexts are mixed or disturbed. Sampling of the deposits finally has to take into account the spatial distribution of the material, to look at variation across a site or a structure (spatial sampling; [Figure 13](#)). For mummified or frozen burials/bodies, small samples from the stomach or clothing may be taken (e.g., see Holden in [Brothwell and Pollard, 2001](#) or [Dickson et al., 2003](#)).

Figure 4 Impression of a cereal ear at the bottom of a pot. The example shows a tetraploid naked wheat (*Triticum durum* Desf./*turgidum* L.) or emmer (*T. dicoccum* Schübl.) from the Neolithic lake shore settlement Arbon Bleiche 3 (3384–3370 BC) at Lake Constance (Switzerland). Similar remains may also be preserved in burnt daub. The original biological fragment has been combusted during firing. Recovery of the Plant Remains, Analysis, Identification, and Quantification

In several textbooks and papers the recovery of plant remains is described ([Figure 14](#); [Pearsall, 2000](#); [Jacomet and Kreuz, 1999](#)). For the recovery of charred remains flotation may be the suitable procedure, however, wet-sieving (combined with a wash-over-technique, see [Kenward et al., 1980](#)) may also be appropriate. A pretreatment is necessary when the sediments contain clay (e.g., slow drying under low temperatures in a drying chamber and a subsequent soaking in water or deep-freezing and thawing). Sieving of waterlogged remains must be performed carefully to prevent the destruction of plant material. The best method is the use of the wash-over-technique with a gentle water jet. For strongly compacted organic sediments experiments showed that deep-freezing and subsequent

Figure 5 Reconstructed farm houses ('pile-dwellings') of the 4th millennium BC at the open air Museum in Unteruhldingen (Germany): Primary material consists of building materials and tools. Secondary material would include charcoal from fires and by-products from construction, while tertiary materials would consist of re-worked primary and secondary material. Photograph © S. Jacomet.

thawing gives excellent results, whereas the use of potassium hydroxide should be avoided because it destroys fine organic parts (Figure 15). In addition, the smallest sieve mesh should be not larger than 250–300 μm . In some cases (high density of desiccated plant remains or charred seeds) the samples may be put straight under the microscope for identification without processing. Those containing some sediment may be first dry sieved. For information about analysis techniques (including subsampling) see the textbooks of Jacomet and Kreuz (1999) and Pearsall (2000). For identification see Körber-Grohne in van Zeist et al. (1991). For the identification of wood see Neumann et al. (2001) and Schweingruber (1990). Of particular importance is a good reference collection. After identification, the grains, seeds, chaff, nutshell fragments, tubers, etc., are quantified for each sample that was investigated. Before a reliable quantification is possible, units which are counted have to be defined (e.g., one spikelet fork of a glume wheat counts as two glume bases). The resultant data are tabulated on a sample-by-sample basis with individual counts for each identified component. The best way to store data is a relational database, which forms also the basis for evaluations (e.g., see Kreuz and Schäfer, 2002).

Figure 6 Sediments which accumulate within negative features left open at abandonment appear to form three distinct stages, here the example of the filling history of a Roman well: The primary fill forms from the weathering of the sides and the contemporary surface soil, very soon after the feature is dug (and is thus the deposit that could usefully be sampled in order to reconstruct the environment at the time of construction). The secondary fill forms after abandonment from material either blowing in, or eroding from, a contemporary soil. Tertiary fills are often deliberately filled by humans with rubbish, dung etc., e.g. to level the feature; they may be plus/minus contemporary to the secondary fill, or much later than the original feature. Reproduced with permission from Greig J (1988). The interpretation of some Roman well fills from the midlands of England. In: Küster H (ed.) *Der prähistorische Mensch und seine Umwelt. Stuttgart: Konrad Theiss Verlag.

Interpreting Proxy-Data from Archaeological Sites

There are many differences in how those who study paleoenvironment and those studying paleoeconomy interpret their data. For the latter, it is of fundamental importance to compare sample data spatially and temporally both across a site, and between sites by examining the proportions of key components. Comparison may be made by using densities, percentages, ubiquities, or more complex statistical techniques (see the textbooks of Jacomet and Kreuz, 1999; Pearsall, 2000; Wilkinson and Stevens, 2003 and Jones 1987; for different examples see the proceedings volumes of the International Work Group for Paleoethnobotany conferences like Behre and Oeggl, 1996; Buxó et al., 2005; and Jacomet et al., 2002). Also worth mentioning is the concept of indicator groups (Hall and Kenward, 2003). In doing an evaluation it is important that samples are examined by class (Table 5), considering taphonomical processes.

Figure 8 Parts of the buildings (wooden shingles, made of silver fir, *Abies alba*) in a destruction layer of Neolithic lakeshore settlement Arbon Bleiche 3 (3384–3370 BC), Lake Constance, Switzerland; these remains were embedded very rapidly after the site burned down, therefore they are preserved. Studying ancient environments based on on-site data uses similar approaches to other paleoecological studies. However, like natural environments, not all archaeological environments have modern analogs as we know from many archaeobotanical investigations of class A samples (Table 5). Especially problematic is that of premodern arable environments (G. Jones, 2002). As a result of these problems, few scientists apply uniformitarian principles rigidly. They use it as a method that can be applied when deemed appropriate rather than a piece of underlying theory which is universally applicable (e.g., see Behre and Jacomet in van Zeist et al., 1991). It also recognizes that the scale of processes that operated in the past, both spatially and temporally, may have been very different from those observed at the present. Some new approaches are mentioned below (see Table 6).

Some Examples of Results

One of the prime goals in archaeology is the deciphering of ancient society: for this, the study of past economies is of fundamental importance. By ‘economy’ archaeobotanists are usually referring to the way people organized the production of food and how foodstuffs were distributed amongst the people and used (consumption; see Wilkinson and Stevens, 2003; how economy can be understood; see Charles and Halstead, 2001, in Brothwell and Pollard, 2001).

Wild Versus Domesticated Plants

Until around 10 000 years ago humans lived as hunters and gatherers; plant fruits such as almond, pistachio, etc., but also roots and tubers were collected from the wild. Around the transition from the Late Glacial to the Holocene, in several parts of the world people began to domesticate plants (Diamond, 2002). For example in the Near East (‘Fertile Crescent’) there were many places where sedentary life began in the upper Paleolithic when

Figure 9 Schematic representation indicating under which depositional environments specific categories of environmental remains can be expected to survive and hence be recovered. If the material is preserved in more-or-less original form and only slightly altered, preservation is called sub-fossil. If the original material is replaced totally, e.g. by charring, preservation is called fossil. The former only survive under specially favorable conditions like waterlogging, the latter under very different conditions, ranging from mineral soils to waterlogged and other conditions. The filled area marks an envelope into which most sediments fit. Reproduced with permission from Jones DM (2002). *Environmental Archaeology, A Guide to the Theory and Practice of Methods, from Sampling and Recovery to Post-Excavation*. Swindon: English Heritage. © English Heritage 2002.

people still lived as hunter-gatherers (e.g., Tell Abu Hureyra in Syria; Hillman et al., 2001; Figure 16). The regular presence of domesticated plants, detectable on the basis of their morphology (Figure 17), is usually noticed in the 'Pre-Pottery-Neolithic B' stage, from 8500 cal yr BC onwards (Figure 3 and Table 7; e.g., Cappers and Bottema, 2002). Recently, new insights into plant domestication have been gained through the results of molecular biology (e.g., see Salamini et al., 2002). Many of these results point to single domestication events. However, based on archaeobotanical data, there is no evidence for a single center of origin; agriculture arose in widely separated geographic and climatic regions. What forced people to begin cultivation is a matter of debate. (see also Table 8).

History of Plant Growing and the Spread of Agriculture

First of all, in the Near East short-lived (annual) plants like cereals (different wheat and barley varieties), flax, and pulses

(pea, lentil, and others) were domesticated (Zohary and Hopf, 2000). This stock of 'founder crops' then spread westwards and reached Central Europe around 5500 cal yr BC (Figure 18). Not all the early domesticated plants reached different parts of Europe together, and the spread of single cultivars is far from being fully understood (for details see Colledge and Conolly, 2007). Concerning wheat species, the agriculture of the early Neolithic Linear Pottery Culture was based on einkorn (*Triticum monococcum*) and emmer (*T. dicoccum*). During the fifth millennium BC hexaploid naked wheat (*Triticum aestivum*) was an important crop in some settlements. In the fourth millennium BC, in the circumalpine Lake Dwellings, a tetraploid naked wheat (*Triticum durum/turgidum*, Figure 10c) played a major role. First sure traces of spelt (*Triticum spelta*) cultivation come from the end of the Neolithic period in Central Europe. This robust glume wheat then became very widespread in Europe during the Bronze Age. The same holds also for millets (*Panicum miliaceum*, *Setaria italica*), domesticated plants originating from

Table 5 Charred plant remain classes, according to Hubbard and Clapham

Class A	Plant material that has burnt in the same location from which it was recovered. This category would encompass several types of burnt storages (see Figure 13), including storage pits that catch fire and hearths and kilns, where the feature and its spent fuel survive in the archaeological record. In these cases the relationship between the context and the plant remains is very strong.
Class B	Plant material that is charred during a single burning event, but where the burnt material has been redeposited, either deliberately or accidentally. The act of redeposition means that the material may not specifically relate to the context in which it was found.
Class C	Material that comes from a number of temporally and spatially distinct burning events and activities. The material from these events is mixed together with settlement waste to become incorporated in archaeological features such as middens, rubbish pits etc. The remains have little if any relationship to the context from which they are recovered.

Adapted from [Wilkinson and Stevens 2003](#), Table 14, p. 152 with permission. Class C forms the so called “background noise” after [Bakels CC \(1991\)](#). China. There are large spatial and temporal differences in the importance of the single cultivated plant species as well as their diversity in the Old World ([Colledge and Conolly, 2007](#)); one of the reasons for this is probably cultural traits.

Only some 1000 years after short-lived plants, woody plants also show traits of domestication. In the Near East, from the Early Bronze Age onwards (about the fourth millennium BC) figs, vines, dates, and olives belong to the domesticates ([Zohary and Hopf, 2000](#)). However, collecting wild plants did not stop after domestication: particularly in northern parts of Europe collecting played a very important role ([Figure 19](#)) until the widespread introduction of gardening during the Roman period. (see also [Table 9](#)).

Applying Biological Evidence to Economic Questions

Processing Techniques, Storage, and Food Preparation

The aim of growing a crop is to obtain a clean product that may be further processed into food. Information about how crops were processed and stored comes from both weed seeds and remains of the cultivated plant itself. After harvest of cereals, for example, the farmer is left with a great deal of mostly undesirable weed seeds, chaff, and straw. Ethnographic work (e.g., [Hillman, 1984](#); [Figure 20](#)) has demonstrated that there are relatively few ways (in the absence of modern machinery) in which the processing sequence of cereals can be carried out. Archaeobotany successfully tried to assign charred assemblages to a single processing stage ([Figure 21](#)). However, often assemblages result from an amalgam of all of the stages needed to obtain clean grain for storage. Then the charred plant remains will only provide information on how much processing had occurred prior to that stage. So, if there were only glumes, grain, and large weed seeds – as in many Roman settlements – it may be concluded that storage was as semiclean spikelets. Alternatively, if there are large numbers of small weed seeds, straw culms, and stems it may be concluded that cereals were stored either as sheaves or as partially threshed ears. After assessing how crops were stored, scientists can begin to examine, for example, the spatial distribution of processing activities and storage. One of many examples is the investigation of a thick layer of carbonized seeds in an eleventh century AD granary from southern France ([Figure 13](#)). In the western part of the granary, naked wheat was stored in bulk. In the eastern part, various crops (at least naked wheat, barley, rye, oat, and grape) were stored in small amounts, most of which were probably separated by light, wooden structures

What the Iceman and his belongings tell us

Figure 12 What the Iceman and his belongings can tell us (clothes, equipment etc.). A: The Iceman was small, standing only 159 cm. Desiccation after he died shriveled the body both externally and internally. Ice pressure deformed his upper lip, nose and ears. He was not bald in life, and he probably had a beard. Some of his hair, up to 9 cm long was found. B: The oldest ax ever found, it has a copper head secured to the yew handle by birch glue and bound with strips of hide. C: The handle of the dagger is ash wood, the sheath is made of limebast-fibers and the lace of grasses. D: Flint sharpening tool made of lime-wood. E: A pouch (made of leather), probably fastened around his waist, contained a fire making kit, including true tinder fungus (*Fomes fomentarius*) and small flints. F: The shoes were carefully stitched from hide (of red deer, the sole of bearskin), inside the net and the isolation was made of grasses. G: The cap was sewn of brown bearskin. The Iceman can be taken as representative of how Neolithic people around 3350 BC would have been dressed and the objects that they would have used. Very few of them are recovered in more conventional archaeological settings. Reproduced with permission from [Dickson et al. 2003](#) (for more details see there).

made from hazelnut, maple, etc. The cereal crops had largely been processed and cleaned. The stored products probably represent taxes paid to the lord who owned the granary.

Although the procedures of processing seem to be efficient, analyses carried out on archaeological bread, dough, excrement, and the contents of the stomachs of bog bodies often show that the operations did not result in clean grain, and bits of chaff, unground grain, and weed seeds still remained in the product eaten by people. Waterlogged plant remains from many bog bodies (at least partly dating to the Late Iron Age) have a rather high amount of weed seeds in their stomachs, as well as cereal chaff; the Grauballe man from Denmark had even whole spikelets of wheat in his stomach (Holden in Brothwell and Pollard, 2001). The excrement of the workers in the salt mines of Hallstatt (Austria; Iron Age) also contained many chaff remains. (see also Table 10).

Production and Consumption

Production and consumption are an integral mesh of activities and relationships (Wilkinson and Stevens, 2003). The most important aspect of production is that of food. Almost all foodstuffs derive from plants (salt is an exception). It was once argued that sites involved in the growing (producers) of plants could be distinguished from those receiving (consumers) plant products. On the one hand it was proposed that grain-rich assemblages from Iron Age Britain represent producer sites and weed/chaff-rich assemblages consumer sites. On the other hand it was argued – based on ethnographical data – that producer sites are characterized by the waste from early stages of crop processing. Therefore, a differentiating of consumer- and producer-sites, based on archaeobotanical evidence only, is difficult. Variation in charred plant assemblages

Figure 17 (a) Differences between wild and domesticated cereals. In the case of cereals, the former have brittle rachises and clean, semicircular disarticulation scars, whereas the latter show tough rachises and a rough breakage of rachis, leaving sharp corners which impede penetration. Reproduced with permission from Hillman GC and Davies MS (1992). Domestication rate in wild wheats and barley under primitive cultivation: preliminary results and archaeological implications of field measurements of selection coefficient. In: Anderson P (ed.) *Préhistoire de l'agriculture: Nouvelles approches expérimentales et ethnographiques*, (Monographie du CRA Vol. 6), p. 113–158. Paris: Editions du CNRS. (b) examples of wild (left side) and domesticated (right side) cereal grains (here carbonized specimen of the glume wheat emmer, *Triticum dicoccum*, from Cayönü, Turkey): The former are smaller, the latter larger (Reproduced with permission from Zohary and Hopf, 2000). The mentioned differences are visible in the archaeobotanical material. However, in early sites it is often difficult to decide to which group a remain should be attributed.

Figure 17 (Cont'd)

from the Late Iron Age in England is, for example, more likely to relate to differing storage practices, for example, of surplus-grain than consumption/production. Only when other – archaeological – evidence is found (Table 2) is a more definitive interpretation possible. However, there are also clear cases of producer units like the Roman *Villae rusticae*. (see also Table 11).

Cultivation Techniques

Much of the information about the cultivation techniques comes from weed seeds. Unfortunately, at each stage of cleaning, processing removes more and more weed seeds, so the cleaner the grain when charred, the less evidence there is of cultivation practices. In any case the first step will be to analyze from which stage of cleaning the weed spectrum derives (Figures 20 and 21). Helpful tools in interpreting weed assemblages are also experimental farming or an ethnoarchaeological approach.

Weed species may be characteristic of environmental factors such as soil types, drainage, climate, and the specific cultivation practices employed by the farmer like manuring, tillage, sowing times, and weeding. This therefore provides a proxy for determining where past crops were grown (G. Jones, 2002). Based on the application of FIBS (Functional Interpretation of Botanical Surveys; Jones et al., 2005) to Neolithic weed spectra, Bogaard (2004) concluded that in those times cereal farming was practiced on small,

intensively worked and manured plots. There are other interpretations, however, including considering shifting cultivation. Larger fields seem to become widespread only from the Metal Ages onwards.

The presence or absence of seeds of weed species from the harvest will depend on the method of harvest. For example, harvesting by sickle will remove cereals, rachises, some culms, and weeds. Harvesting low on the culm will bring in not only these weeds but also seeds of low-growing species such as clover (*Trifolium* sp.). Finds of many low-growing weeds from Late Bronze Age and Iron Age settlements in Europe suggest that harvesting was carried out with sickles or scythes (of which also evidence is found) low down the stem whereas in early Neolithic times high-growing weeds prevailed which points to totally different harvesting methods.

Archaeobotanical investigations will allow the determination of the weed species composition of an arable field to some extent. However, an interpretation of the ratio of perennial-to-annual weeds concerning the type of tillage is not as straightforward (Bogaard, 2002) as thought. Newest results point to the fact that already in Neolithic times fields were intensely worked even though they contained more species of perennial weeds (e.g., creeping buttercup *Ranunculus repens*); these reproduce from fragments of root stem and so in fact benefit by more effective tillage. Only later, for example in medieval times, were crops with dominating annual species found, pointing to a permanent cultivation

Reproduced with permission from Nesbitt M (2002). When and where did domesticated cereals first occur in southwest Asia? In: Cappers RTJ and Bottema S (eds.) *The Dawn of Farming in the Near East*, (Studies in Early Near Eastern Production, Subsistence, and Environment Vol. 6), p. 113–132. Berlin: ex oriente.

of larger fields. The presence of winter annuals from Neolithic times onwards points to winter- and summer-cropping.

Usually, there are many lines of evidence that crops were grown separately. However, there are also hints on mixtures of crops in several periods. This seems to be reasonable as a risk-minimizing strategy. However, another possibility is that those crops were grown as fodder (see also Table 12).

Some Other Aspects of Archaeobotanical Research

There are many more aspects of archaeobotanical research of which only some can be mentioned here. The analysis of plant remains from animal dung allows a thorough

reconstruction of their fodder. Wood was carefully chosen depending on its properties. First traces of widespread grassland occurred in northern parts of Europe from the Bronze and mainly the Iron Age onwards. In parts of Europe, north of the Alps since the Roman period there was widespread trade. 'Exotic' species like pomegranates, dates, pepper, anis, etc. appear already in early Roman contexts. It is also obvious that gardening was introduced by the Romans in regions outside the Mediterranean. Cultivated cherry, apple, peach, walnut, etc., but also legumes and spices like coriander are regularly found north of the Alps from Roman times onwards. There are hints that some 'luxurious' foodstuffs were eaten only by socially higher ranked people like officers of the army (van der Veen, 2003). There were also fundamental

differences between the ‘mass production’ of food in the roman villas and agriculture outside the Roman empire (e.g., in the *Germania libera*).

The interpretation of bioarchaeological material may allow also the reconstruction of aspects of rituals ([Wilkinson and Stevens, 2003](#)). These are actions that are associated consciously or subconsciously with symbolic meaning. For instance, many burials have ecofacts that are buried with them, such as plant remains that accompany artifacts and personal belongings. These may be remains of funeral feasts, food to sustain the individual on their journey to or within the afterlife, or offerings to buy their way in. Desiccated offerings of plant foods are a frequent feature of Egyptian burials. Many plant offerings including figs, dates, grain, sesame, and wreaths of lotus, olive, willow, cornflowers, mayweeds, and various fruits were found in Tutankhamen’s tomb. In incineration graves from the Roman period many carbonized food remains can be found. From temples, remains of burnt food offerings have been recorded from Roman Europe. (see also [Table 13](#)).
